## 1 INTRODUCTION

## 1.1 PROJECT PURPOSE

The South Dayton Valley Area Drainage Master Plan (SDVADMP) was developed to meet three primary objectives:

- Evaluate and identify flooding and sedimentation hazards within the project area by completion of a technical study that includes data collection, review of previous studies, information gathering from public agencies and residents, hydrologic and hydraulic modeling, geomorphic assessments, and field surveys.
- 2. Develop a series of alternatives to either partially or wholly mitigate the hazards identified in the first objective.
- 3. Provide stakeholder coordination and public outreach of the project through a series of public meetings to inform of the existing hazards and to present the mitigation alternatives.

Each major task of the project is presented herein with a description of the technical approach, analysis results, interpretation of results, and applicability to the overall project purpose. The results of this study can be used as a planning tool and as input to the design of potential future drainage infrastructure and flood mitigation measures that are appropriate for the physical environment for both existing and future development.

## 1.2 PROJECT LOCATION

The SDVADMP study area is 97 square miles and is located on the northern slopes of the Pine Nut Mountains, approximately 15 miles east of Carson City (Figure 1-1). Most of the study area spans Lyon County, with smaller portions of the upper watershed extending into Carson City and Douglas Counties. The percent study area by county is: Lyon County (75%), Carson City County (16%), and Douglas County (9%). The primary focus area of the SDVADMP is the lower watershed area downstream of the mountains, also shown on Figure 1-1.

1

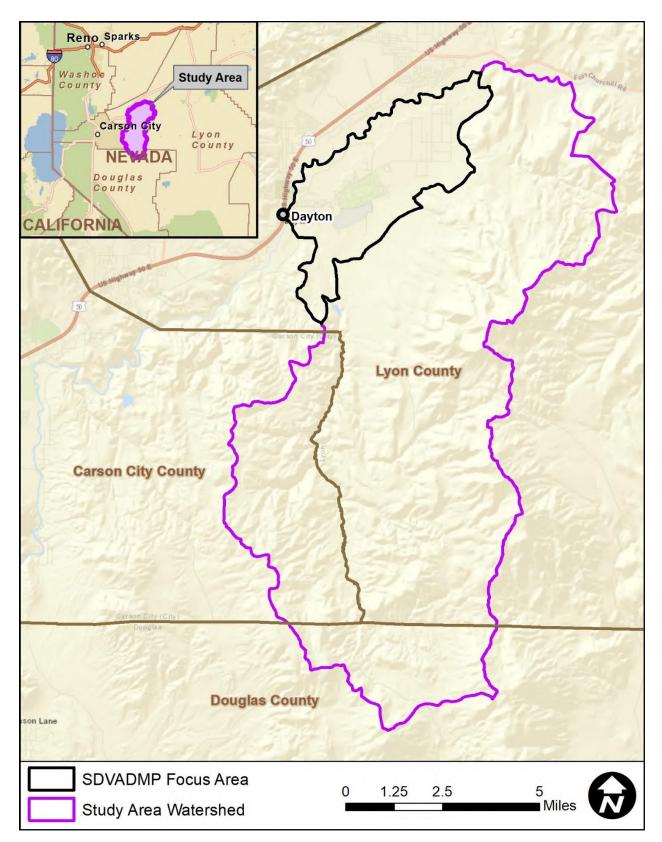

Figure 1-1. Study area vicinity map

## 1.3 PREVIOUS STUDIES

An early phase of the study included research and collection of previous reports and studies relevant to the ADMP area. These included drainage reports for local subdivisions, flood insurance studies (FIS), and geologic reports. A summary of the different types of reports are summarized in the following sections.

## 1.3.1 Subdivision Drainage Reports

Several drainage reports and drainage studies were collected from the county agencies and included information that was used directly in the development of the existing conditions hydraulic model (Section 2). The documents provided information on the location and design for drainage facilities within the individual subdivisions. All the collected drainage reports are included in the digital data appendix (Appendix C). Table 1-1 lists the collected documents.

Title	Author	Date	Subdivision
	Drainage Reports a	nd Drainage Studies	
Dayton Valley Country Club	Summit Engineering	August 2000	Dayton Valley Country Club
Final Drainage Study for Riverpark Unit 20	HEC Civil Engineering Consultants	August 2005	Riverpark Unit 20
Drainage Report for Webstaurant Building Expansion	Tectonics Design Group	September 2015	Airpark
Conceptual Drainage Analysis for the Gold Canyon Estates Phase 2	Western Engineering & Surveying Services	July 2004	Gold Canyon Estates
Technical Drainage Study for Granite Pointe Subdivision	R.O. Anderson Engineering, Inc.	December 2016	Granite Pointe
Hydrologic Drainage Report for Gallery Phase 3A Residential Development	Manhard Consulting	December 2017	Gallery Phase 3A
Hydrologic Drainage Report for Point Legado Phase 2 Residential Development	Manhard Consulting	February 2018	Point Legado
Drainage Study for the Holley Ranch Estates Tentative Map	Lumos & Associates	August 2018	Holley Ranch Estates
Hydrologic Drainage Report for Gallery Phase 3A Residential Development	Manhard Consulting	September 2018	Gallery

Table 1-1.	Collected	subdivision	drainage rep	orts
------------	-----------	-------------	--------------	------

#### 1.3.2 Flood Insurance Studies

Federal Emergency Management Agency (FEMA) Flood Insurance Studies (FIS) for Lyon County were collected and reviewed for historical flooding records and regulatory discharge estimates for watercourses in the study area. Table 1-2 lists the collected studies and derived information. Although the goal of this study is not to "match" the FIS discharge estimates, they do provide a base-level comparison for the hydraulic model results (see Section 2.3). The consistency of discharges between years in Table 1-2 suggests that there has been no revision to the hydrology for FEMA regulatory studies since at least 1998.

Study Date	County	SDVADMP Watercourses	10-year Discharge (cfs)	50-year Discharge (cfs)	100-year Discharge (cfs)
January 1998	Lyon	Eldorado Canyon	-	-	5,265
February 2000	Lyon	Eldorado Canyon	-	-	5,265
January 2009	Lyon	Eldorado Canyon	-	-	5,265
January 2016	Lyon (current effective)	Eldorado Canyon	-	-	5,265

#### Table 1-2. Flood Insurance Studies

## 1.3.2.1 Effective FEMA Floodplain Mapping

As of the date of this study Eldorado Canyon is the only watercourse in the study area with FEMA regulatory floodplains (Figure 1-2). Table 1-3 lists the descriptions for each flood zone within the study area. Like FIS data, FEMA floodplain mapping provides a base-level comparison of flood risk for the hydraulic modeling results from this study.

#### Table 1-3. FEMA flood zones within the study area

Flood Zone	Definition	Flooding Type	Recurrence Interval
А	No base flood elevation is provided	Riverine	1% chance
AE	Base flood elevation (BFE) is provided	Riverine	1% chance
AE with Floodway	BFE and Floodway is provided	Riverine	1% chance
Х	Flooding outside the SFHA	Riverine, Other	0.2% chance
Х	Area of minimal flood hazard	Riverine, Other	-

4

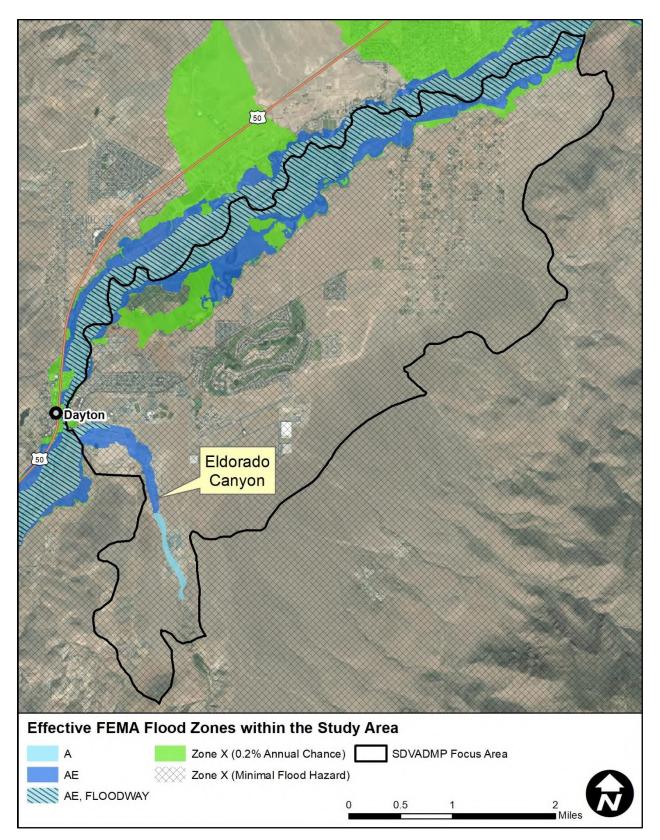

Figure 1-2. Effective FEMA Floodplains

### 1.3.3 U.S. Army Corps of Engineers Alluvial Fan Mapping

In December 2017 the U.S. Army Corps of Engineers (USACE), Sacramento District, published a study titled *Alluvial Fan Mapping for the Carson River Watershed Methodology* (Floyd, 2017) which included the SDVADMP study area. The purpose of the mapping study was to classify the relative risk of alluvial fan landforms within the Carson River Watershed. Alluvial fan landforms were identified and assigned a risk ranking based on the following categories:

- Appearance of active or inactive
- Existence of disturbances
- Presence of infrastructure

Within each category, a series of risk factors were examined. For example, the Active/Inactive category included four risk factors:

- o Soil Development
- o Alluvium
- o Unconfined Flow
- o Incised Channels

The risk factors were assigned a relative score and summed to derive an overall hazard ranking by watershed. Figure 1-3 from the report depicts the distribution of relative risk rankings by watershed. Figure 1-4 shows the identified alluvial fan landforms within the SDVADMP study area and their assigned risk.

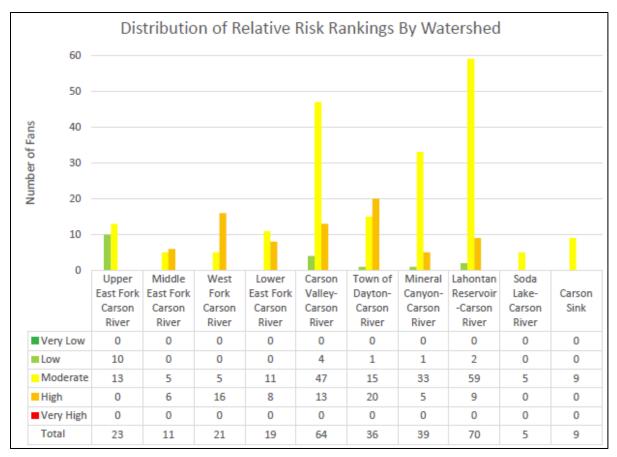

Figure 1-3. Distribution of relative risk rankings by watershed, from Floyd (2017)

7

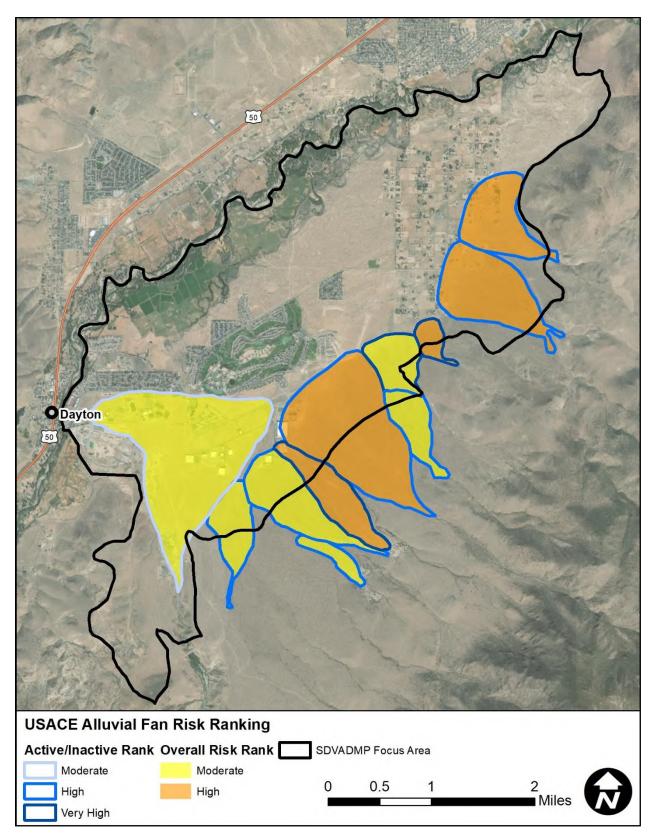

Figure 1-4. USACE alluvial fan risk ranking

## 1.4 HISTORICAL FLOWPATH ASSESSMENT

Understanding the historical evolution of a geomorphic system is critical to understanding present-day processes and predicting future trends. Natural systems can take hundreds of thousands of years to develop, and their morphology is a direct reflection of this long-development period. Anthropogenic changes to a natural system often result in abrupt changes that can be managed for a brief period, but quite often the disturbed system will trend back to its natural condition, despite efforts to change and maintain it.

A historical flowpath assessment was conducted for the DVADMP study area to assess the natural flowpaths of the study watercourses with the goal that understanding the natural flowpaths will aid in understanding the current flooding patterns and potential future flooding trends.

## 1.4.1 Aerial Photography

Historical aerial photography from 1948 (earliest year available) and 1953 were collected and semirectified using ArcGIS software tools. The 1948 photography was not available for the entire focus area, so the next available year of photography (1953) was used to complete the dataset. The natural flowpaths for the project watercourses were identified and delineated from the photography. Figure 1-5 shows the 1948/1953 aerial photography and Figure 1-6 the modern aerial photography (2018) for the ADMP focus area. The 1948/1953 photographs pre-date much of the development within the focus area and shows the landforms in a (mostly) natural condition. The locations of the dominant flowpaths for the major drainage channels were interpreted and delineated from the 1948/1953 photographs to compare with the present-day locations.

## 1.4.2 Summary

The most significant changes in flowpath alignment since 1948/1953 have occurred due to manmade channel realignments (Figure 1-7). Both the historical and modern aerial photography indicate evidence of distributary and active alluvial fan drainage patterns within the project focus area, but many of the main drainage channels have remained laterally stable for at least the past 70 years. This suggests that there may not have been a flood event of sufficient magnitude since at least 1948 to cause major channel avulsions. The major watercourses were investigated during the field verification phase of the ADMP and were not found to be incised or laterally confined within the lower project focus area. In other words, there are no physical constraints that should have prevented historical channel avulsions since 1948, which further suggests that there hasn't been a flood event with sufficient energy to cause a major channel avulsion. As such, flowpath uncertainty scenarios are not recommended for this study area as they were in the Dayton Valley ADMP.

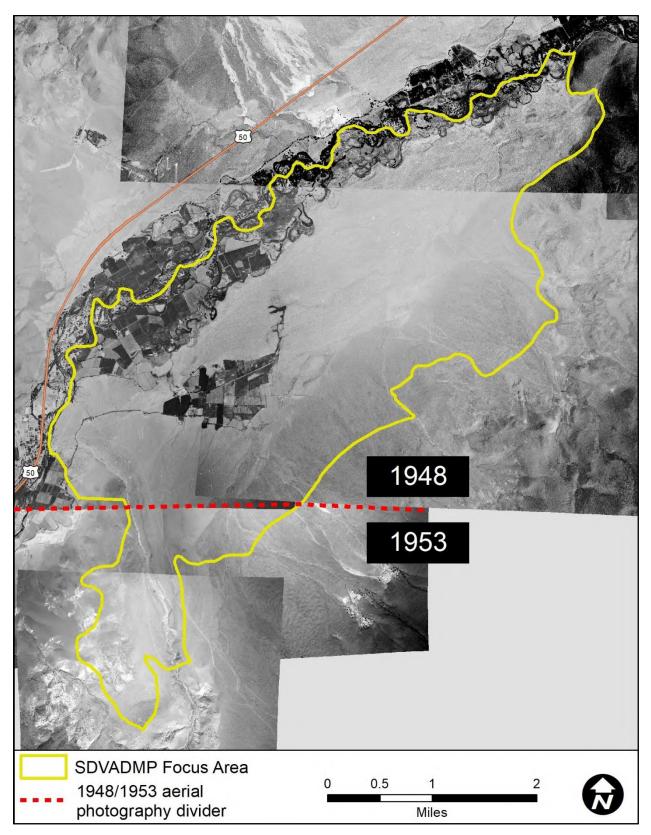

Figure 1-5. 1948 aerial photography

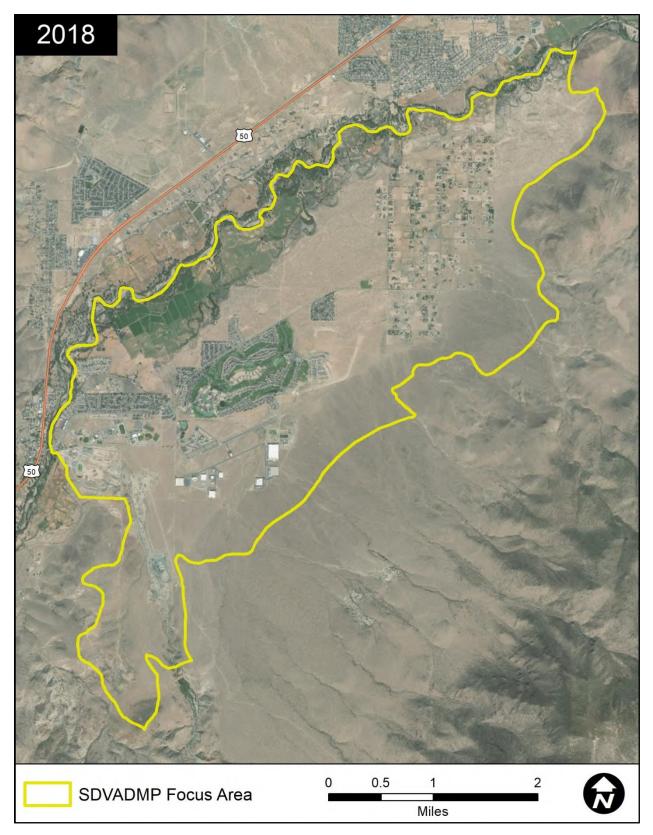

Figure 1-6. 2017 aerial photography

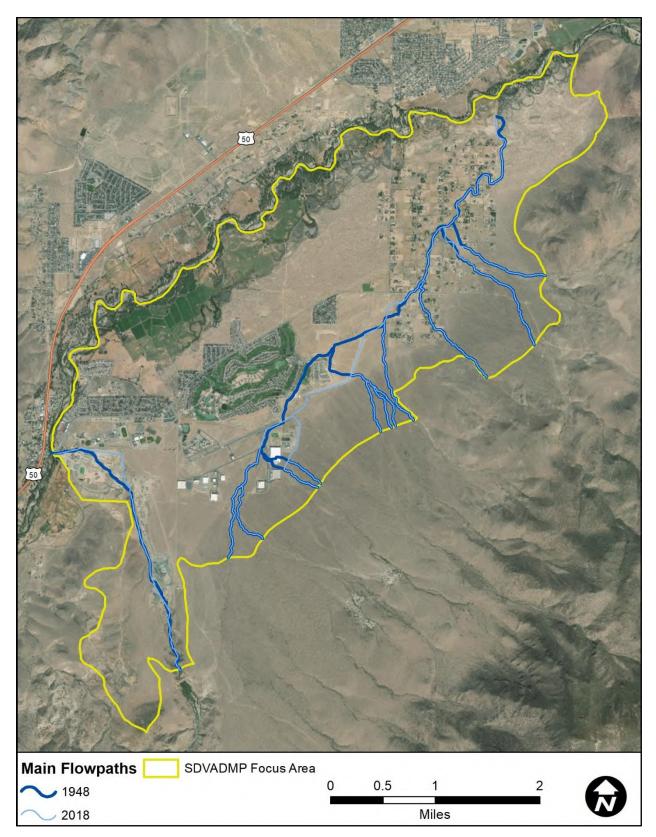

Figure 1-7. Historical flowpath comparison

## 2 HYDROLOGIC AND HYDRAULIC MODELING

## 2.1 METHOD DESCRIPTION

To maintain consistency with the adjacent Dayton Valley Area Drainage Master Plan (DVADMP), the same general procedures were used in model development. The procedures that were used for hydrology and infiltration for the SDVADMP are as follows:

- Infiltration was simulated using runoff curve number (CN) methodology per the Lyon County Drainage Guidelines (2018).
- Rainfall depths were based on the NOAA Atlas 14 (NOAA14) precipitation estimates.
- The hyetograph for the 6-hour storm was based on the balanced mass curve, while the hyetographs for the 24-hour storms were based on the Nevada Department of Transportation (NDOT) 90th percentile maximum intensity with smoothing by the generalized logistic equation (GLE) (NDOT, 2015).

All modeling, both hydrologic and hydraulic, was done using the FLO-2D Pro software<sup>1</sup> package, Build No. 16.06.16 with an executable dated February 28, 2017. This version has been used for multiple area drainage master studies and has functioned adequately. FLO-2D was selected for the SDVADMP due to the following: 1) to maintain method consistency with other ADMPs and drainage studies in the area (Manhard, 2012; JEF, 2019), 2) to streamline model development since there are many small subbasins that would require individual analysis if a lumped parameter model, such as HEC-HMS were used, and 3) FLO-2D is a combined rainfall-runoff model (i.e., both hydrologic and hydraulic processes are simulated within the model).

## 2.2 MODEL DEVELOPMENT

## 2.2.1 Spatial Reference System

All data that was generated for the SDVADMP used the horizontal control of the Nevada Coordinate System, West Zone, NAD83; while the vertical datum was the North American Vertical Datum of 1988 (NAVD 88). The units of measurement were US survey feet.

## 2.2.2 Model Domains

The boundaries of the modeling domains are shown in Figure 2-1. The upper watershed areas (Eldorado and Upper) were modeled to provide inflow hydrographs to the detailed modeling area, labeled as "Lower" in the figure. The upper watershed areas may also be referred to as "off-site areas" throughout this report since the detailed model area is the focus of the flood hazard identification and mitigation alternative development.

Since FLO-2D is a combined rainfall-runoff model, off-site modeling was completed using less detailed models (by surface classification and culvert/storm drain modeling), with inflow hydrographs from these upstream FLO-2D models being transferred to the upstream boundary of the detailed FLO-2D model.

<sup>&</sup>lt;sup>1</sup> https://www.flo-2d.com/

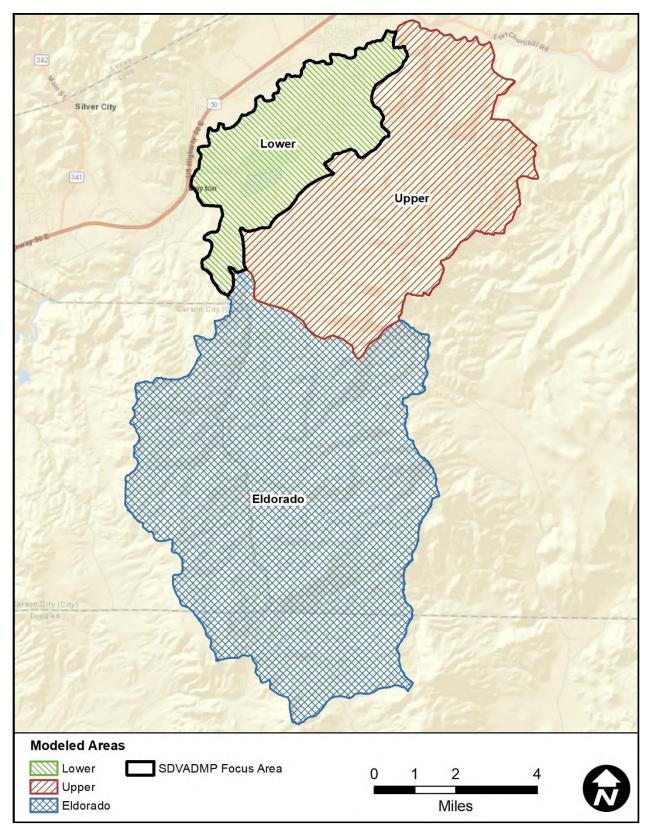

Figure 2-1. Modeling domains used in the South Dayton Valley ADMP

## 2.2.3 Grid Size

The South Dayton Valley watersheds contain many small drainage features that need to be adequately captured in the model to provide the most accurate results. Some of these features include small 18-inch storm drains and minor drainage ditches. A high-resolution, 10-foot grid-size was selected to provide the necessary detail to model these features in the Lower model, while a lower resolution grid size of 20-feet was selected for the two off-site model domains (Eldorado and Upper). The coarser grid size was selected to reduce model run times given the large contributing watersheds. The domain area and the number of grid cells in each model are shown in Table 2-1.

Model Domain	Domain Area (sq. miles)	Number of Grid Elements
Lower	13.5	3,764,732
Upper	29.4	2,054,509
Eldorado	54.4	3,799,432

Table 2-1. FLO-2D model domain areas and number of grid elements

#### 2.2.4 Grid Element Elevations

The limits of all the topographic mapping sources used in the FLO-2D modeling are shown in relation to the model domains on Figure 2-2. There were three mapping sources:

- QL1 LiDAR
- QL2 LIDAR
- NEXTMap 5-meter DTM

All three mapping sources are discussed in detail below.

## 2.2.4.1 United State Geological Survey (USGS) LiDAR

As a part of the 3D Elevation Program<sup>2</sup>, the USGS collected high resolution LiDAR data for a large portion of Carson City and Washoe, Storey, and Lyon counties in Nevada through a contract with Digital Aerial Solutions, LLC (DAS) – Contract Number: G16PC00044. This data was collected at two specifications, QL1 and QL2. The flight parameters and point densities for both datasets are listed in Table 2-2. LiDAR collection began on September 19, 2017 and was completed on October 27, 2017 (DAS, 2018b). The original LiDAR data was collected with elevations in meters, a horizontal spatial reference of UTM Zone 11 N, Meters, NAD83, and a vertical spatial reference of NAVD 88. The DAS LiDAR reports are included in Appendix A.

<sup>&</sup>lt;sup>2</sup> https://www.usgs.gov/core-science-systems/ngp/3dep

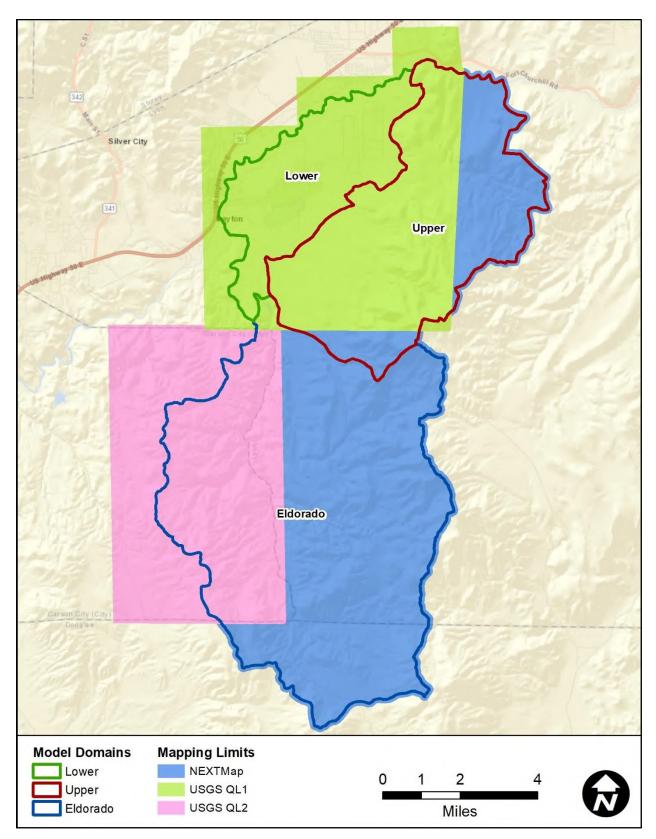

Figure 2-2. Limits of topographic mapping data

Parameter	QL1	QL2
Flying Height Above Ground Level:	8,609 feet	9,072 feet
Nominal Sidelap:	60%	30%
Nominal Speed Over Ground:	155 Knots	155 Knots
Field of View:	15°	24°
Laser Rate:	220.2 kHz	206.2 kHz
Scan Rate:	65.2 Hz	49.2 Hz
Maximum Cross Track Spacing:	1.22 meters	1.62 meters
Maximum Along Track Spacing:	0.61 meters	0.81 meters
Average point Spacing:	0.50 meters	0.67 meters

Table 2-2. LiDAR flight parameters, reproduced from DAS (2018b)

## 2.2.4.2 NEXTMap Data

Approximately 46 square miles of the off-site areas (outside of the SDVADMP focus area) was not included in the USGS LiDAR mapping area. Topographic data (DTM) was purchased from Intermap<sup>3</sup> for this area. This DTM product (referred to as NEXTMap) has a 5-meter resolution with elevation values in meters, a horizontal spatial reference of GCS North American 1983, and a vertical spatial reference of NAVD 88. Initial FLO-2D results from the NEXTMap data were reasonable and compared well with observed flow patterns on aerial photography.

## 2.2.4.3 Combined FLO-2D Data

Since the LiDAR and NEXTMap data were both in meters and in a different horizontal coordinate system than the DVADMP, the data was first converted to feet and the Nevada Coordinate System, West Zone, NAD83 and combined into a single raster. This single raster had a grid resolution of 1-foot to maintain accuracy of the LiDAR data even though the NEXTMap data has a courser resolution. This high-resolution raster was resampled to 10-foot and 20-foot rasters that reflect the average grid elevations that are used in the actual FLO-2D models. The 10-foot grid was used in the Lower model domain, while the 20-foot grid was used in the Eldorado and Upper model domains. The three topographic sources and their relation to the FLO-2D model domains are shown in Figure 2-2.

## 2.2.5 Model Inflow/Outflow

In general, outflow nodes were placed along the entire boundary of the all model domains to let water free-flow out of the domain. For model boundaries that were coincident to a downstream model (i.e., Upper to Lower and Eldorado to Lower), the outflow hydrographs were read from the outflow node and applied to the lower model as an inflow hydrograph. Since the two upper watersheds have a coarser grid spacing than the lower model, the outflow hydrograph was sometimes spit across two inflow elements with the outflow hydrograph being divided by two before being applied as an inflow hydrograph. Note that some outflow elements do not have any outflow; and therefore, a corresponding inflow element does not exist. Also, the model boundary between the Upper and Eldorado models was set along a watershed divide so that there is no flow transfer between these models. A schematic of the flow transfer between models is shown as Figure 2-3.

<sup>&</sup>lt;sup>3</sup> http://www.intermap.com/

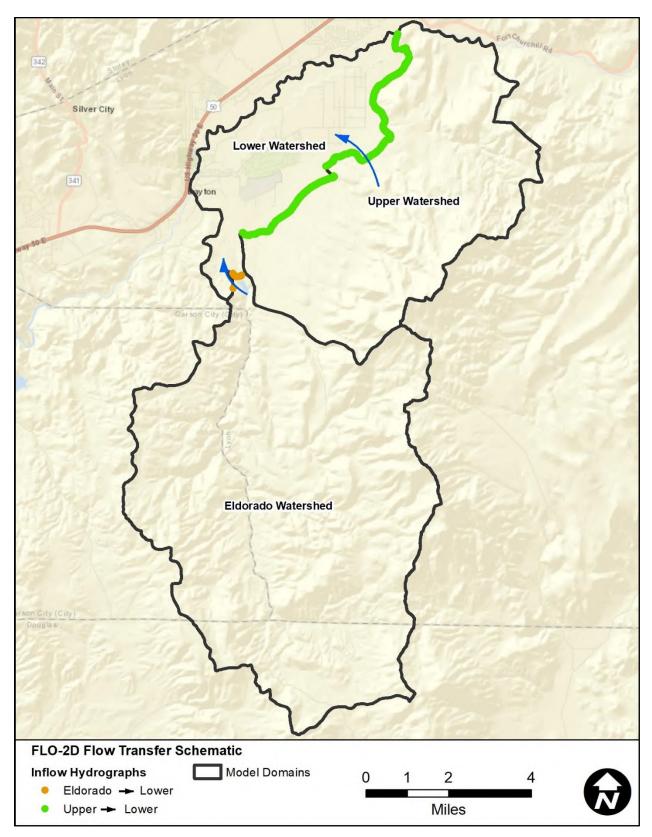

Figure 2-3. Hydrograph flow transfer between FLO-2D models

#### 2.2.6 Precipitation Development

As a part of the SDVADMP, three design storms were simulated:

- 25-year, 24-hour
- 100-year, 24- hour
- 100-year, 6-hour

The 24-hour durations were chosen to be consistent with Lyon County's drainage regulations, while the 6-hour duration was chosen because this higher intensity duration usually results in higher peak flow estimates for smaller (i.e., < 20 square miles) drainage areas.

#### 2.2.6.1 Precipitation Depths

NOAA Atlas 14 (NOAA14) precipitation depth estimates were downloaded from the National Weather Service (NWS) website (2018) as raster images, then used to apply the spatially varied rainfall estimate for each grid element in the model. This means that the point statistics are used at each grid cell in the FLO-2D model, which is different than the typical centroid-based precipitation estimates that are used in lumped parameter (e.g., HEC-HMS or HEC-1) modeling. Point rainfall statistics were selected because:

- 1) using point rainfall has been the general procedure for other ADMP studies in the southwest
- 2) using point statistics results in reasonable but conservative flow estimates. The maximum rainfall point values for each submodel are shown in Table 2-3.

Model	Storm Event		
Domain	25Y24H	100Y6H	100Y24H
Lower	2.268	1.755	2.884
Upper	3.902	2.273	5.046
Eldorado	4.482	2.450	5.819

Table 2-3. Maximum NOAA14 point rainfall estimates (in inches) by recurrence interval and model domain

## 2.2.6.2 Hyetographs

As mentioned in Section 2.1, this ADMP followed the procedures that were developed during the DVADMP. This means that the NDOT (2015) hyetograph for this region was be used for the 24-hour storms, while the "balanced storm" hyetograph (developed with HEC-HMS frequency storm option) was used for the 6-hour duration. Since this area also shows a large increase in precipitation depth when the duration increases from 6 to 24 hours (see Table 2-3), the use of the hyetographs is appropriate. A comparison of the final two temporal distributions that were used in the SDVADMP is shown in Figure 2-4. The hyetographs from the DVADMP are included for reference.

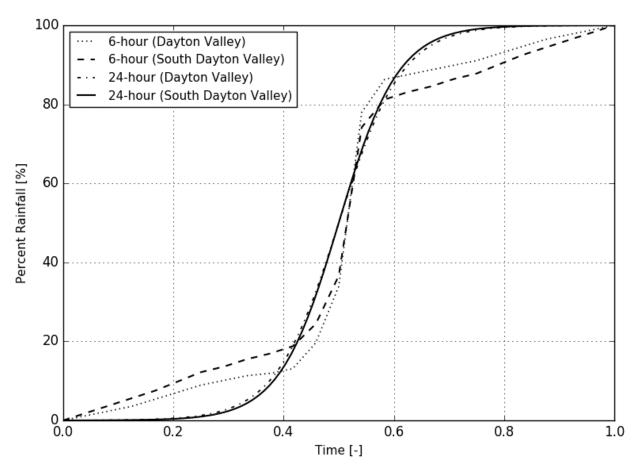

Figure 2-4. Comparison of 6- and 24-hour hyetographs used in the SDVADMP (with comparison to DVADMP)

## 2.2.7 Infiltration Development

As mentioned in Section 2.1, the curve number methodology was used to calculate infiltration for this study. Curve numbers were extracted from the NRCS National Engineering Handbook (2004) which relates hydrologic soil group (HSG) and vegetation coverage type (Table 2-4). The HSG was developed from the Soil Survey Geographic (SSURGO) data from the National Resource Conservation Service (NRCS), which was downloaded from the web soil survey (NRCS, 2019). The spatial variability of the HSG is shown in Figure 2-5.

Initially, curve numbers were assigned using the same procedure that was used in the Dayton Valley ADMP. However, these values produced unreasonable peak flows within the Eldorado modeling domain. Therefore, a more refined delineation of cover type (Pinyon-juniper or Sage-grass) was developed. This delineation is shown as Figure 2-6. Reasonable curve numbers were then selected based on this delineation, Table 2-4, the HSG of the soils, and an adjustment to account for surface imperviousness of pavement (or buildings). The final curve numbers selected for use in the FLO-2D models are shown in Figure 2-7 and listed in Table 2-5.

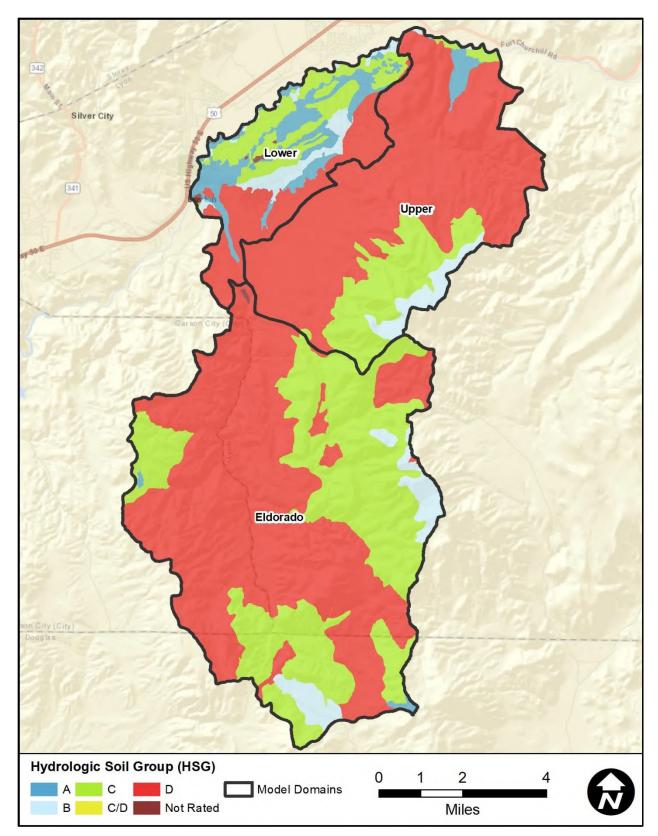

Figure 2-5. Hydrologic Soil Group (HSG) classifications in the South Dayton Valley ADMP, from NRCS (2019)

Cover description		Hydrologic soil gro			up
covertype	hydrologic condition <sup>2/</sup>	A <sup>3/</sup>	В	č	D
Herbaceous—mixture of grass, weeds and low-growing	Poor		80	87	93
brush, with brush the minor element	Fair		71	81	89
	Good		62	74	85
Oak-aspen—mountain brush mixture of oak brush, aspen,	Poor		66	74	79
mountain mahogany, bitter brush, maple, and other brush	Fair		48	57	63

#### 2.2.8 Grid Element Roughness (Manning's n Values)

The FLO-2D model uses Manning's n value to estimate roughness on each grid. Each grid element is assigned an average n value based on the underlying surface conditions. For this study, a detailed surface feature classification was developed by refining land use data provided by Lyon County and adding more detail in areas where the initial delineations were too generalized. For example, major areas of pavement (parking lots and roads) and wash corridors were delineated in the modeling area since these features can act as major conveyances. Buildings and other structures were also added based on the latest available aerials (see Section 2.2.10).

Table 2-6 lists the surface classification and its corresponding Manning's n values that were used in this analysis. Higher values were used for the lower watershed and wash classifications than what was used in the Dayton Valley ADMP due to the increased roughness that was found in South Dayton watersheds (see example in Figure 2-8). The spatial distribution of the surface classification is shown in Figure 2-9.

Surface Classification	Manning's N		
Upper Watershed	0.060		
Lower Watershed	0.050		
Maintained Grass	0.040		
Pavement	0.020		
Buildings	0.050		
Washes	0.045		
Water	0.040

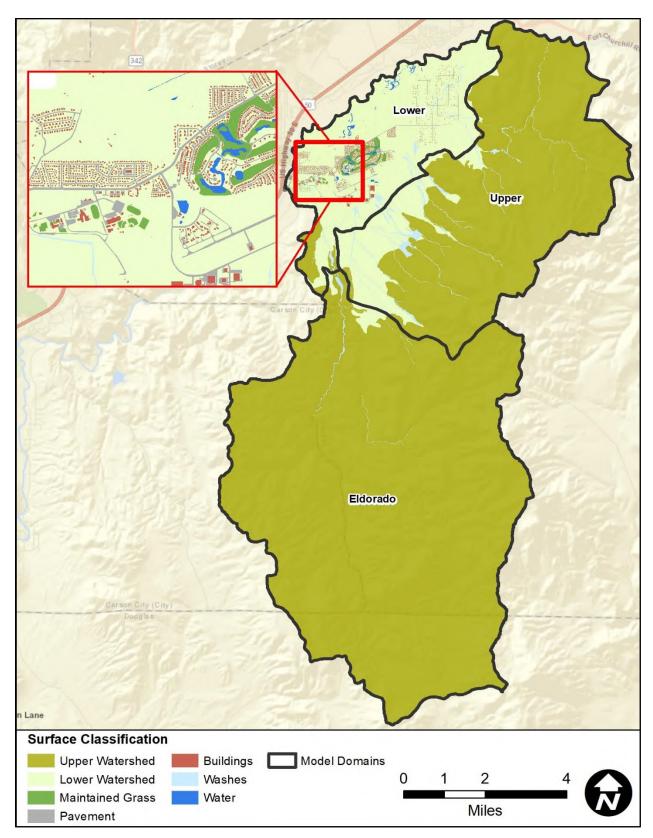

Figure 2-9. Surface classification used to assign grid element roughness in the FLO-2D model

#### 2.2.9 Hydraulic Structures

Both culverts and minor storm drains in the study area were simulated with the hydraulic structure routine within the FLO-2D software. Please see the FLO-2D Data Input Manual (FLO-2D Software, Inc., 2016) and the FLO-2D Reference Manual (FLO-2D Software, Inc., 2017) for more details on the application of this routine and its associated modeling options for this build of the FLO-2D software. All structures (culverts and storm drains) that were modeled as a part of this ADMP are shown in Figure 2-10. Lyon County provided the consultant team with plan sheets which included the location and size of most structures within master planned communities. Additionally, JEF staff conducted two field verification visits to the study area (March 2019 and August 2019) to both locate additional structures and verify the information developed from the plan sheets (e.g. locations, sizes, overall condition, etc.).

## 2.2.9.1 Culverts

In 2016, the Flood Control District of Maricopa County (FCDMC) produced a comprehensive FLO-2D verification report in which recommendations on modeling hydraulic structures were provided. Per those recommendations, the generalized culvert equation option in FLO-2D was used in the South Dayton Valley ADMP models for single barrel box and circular culverts as a first option. If there were multiple barrels, a rating table was developed assuming inlet control for the culvert. The modeling options that were used to model culverts are summarized in the list below.

- 1) Generalized culvert equations used for single barrel boxes and circular culverts with no tailwater influence (i.e., INOUTCONT parameter set to 0).
- 2) If multiple barrel, a rating table developed based on inlet control.
- 3) If significant sediment blockage, most times a rating table developed based on inlet control with a reduced discharge based on the percent clogged. In one case, the height was reduced on a single barrel box culvert to account for sediment deposition.
- 4) If culvert had an irregular shape (i.e., ellipse or arch), a rating table was developed based on a simplified EPA-SWMM model (and the flow reduced if there was significant sediment blockage).
- 5) If tailwater conditions could affect flow, a rating table was used and the INOUTCONT parameter in FLO-2D was set to 2.

## 2.2.9.1.1 Clogging Factors

If a culvert was observed to have significant sediment blockage during a field investigation, an appropriate reduction in flow was applied to the rating table or the open area (i.e., if a culvert was blocked by 50%, the flow or open area was reduced by 50%).

For the detailed on-site modeling (i.e., the Lower model), smaller culverts (<36 inches) used a 50% clogging factor. Larger culverts ( $\geq$  36 inches and box culverts) did not have a clogging factor except where sediment deposition was observed at the culvert or in the watersheds that exhibited high sediment transport rates. The larger culverts that used a clogging factor were denoted by adding a "clog" or "clg" to the name of the structure in the FLO-2D HYSTRUC.DAT input file.

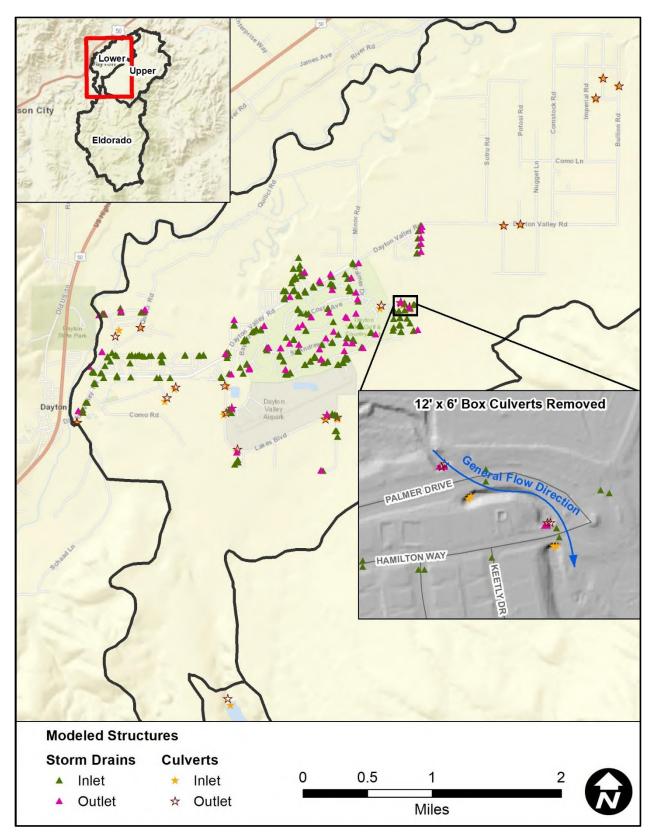

Figure 2-10. Locations of all modeled hydraulic structures (storm drains and culverts)

#### 2.2.9.1.2 Special Problems

Four 12-ft by 6-ft box culverts (within the Lakes at Dayton Valley Village 9 subdivision, see inset map on Figure 2-10) showed erroneous depth results during initial simulations. This area was reviewed, and it was found that water flanks these culverts and enters the incomplete downstream channel first before flowing through these culverts to the upstream channel/basin. Since this water is basically in a ponded condition, an INOUTCONT value of 2 was used for these culverts to allow for reverse flow. However, the box culvert with cell numbers (or ID) 2073538 and 2098000 showed severe oscillations in water surface elevation (WSEL) – see left chart in Figure 2-11. These oscillations appeared to cause a higher depth in the northernmost section of this channel/basin. Consequently, these culverts were removed, and cells lowered to allow for the overland flow routine within FLO-2D to calculate the hydraulics through the open area of these culverts (see Section 2.2.11 for other model adjustments). A comparison of the water surface elevations at the four cell locations (inlet and outlet of two culverts) between the "with" and "without" box culverts scenarios is shown as Figure 2-11. The "without" box culvert scenario shows much more reasonable results when compared with the "with" culverts scenario. Therefore, the final Lower models do not contain the four 12-ft by 6-ft box culverts.

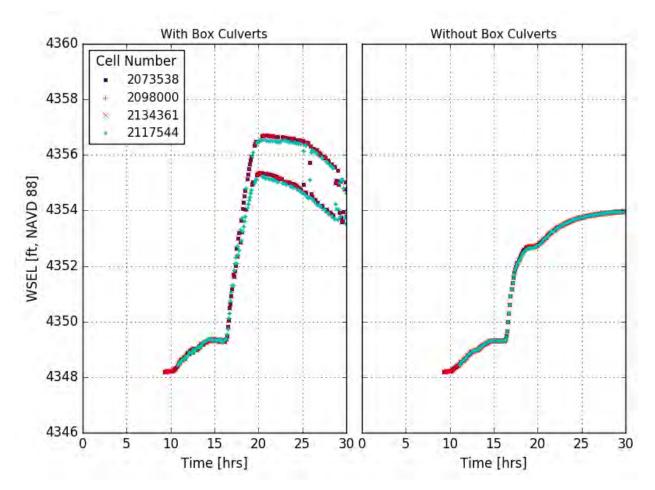

Figure 2-11. Comparison of water surface elevations at the upstream/downstream inlet and outlet cell location with (left) and without (right) box culverts.

#### 2.2.9.2 Storm Drains

Since the study area has a relatively small number of minor storm drains (i.e., 12- to 36-inch trunk lines with about 2 to 10 total inlets per trunk line), rating tables were developed to simulate these structures. The rating tables were developed based on the inlet geometry and the connector pipe. This means that at low depths the curb/grate opening controlled flow, but at higher depths the connector pipe capacity controlled. Finally, if multiple inlets were connected to one trunk line outlet, the "D" line functionality that limits the total flow in the storm drain system to a user-specified discharge was used to limit the flow to the trunk line capacity. This capacity was determined by calculating the normal depth full flow of the trunk line and estimated a 20-50% increase in flow to account for some pressure flow. The limited pipe capacities that were used in the FLO-2D modeling are shown in Table 2-7.

Pipe Diameter	Full Flow (normal depth)	Pipe Capacity in FLO-2D
inches	cfs	cfs
12	6	9
15	10	15
18	17	25
21	25	33
24	36	48
30	65	78
36	105	126

Table 2-7. Full flow versus "D" line pipe capacity used in the FLO-2D modeling

### 2.2.10 Buildings (as Flow Obstructions)

As a part of the OpenStreetMap project, the Microsoft Bing Maps team developed techniques to automatically digitize building footprints from aerials<sup>4</sup>. These automated routines were used to create building coverages for all 50 US states. The buildings shapefile for Nevada was downloaded from Microsoft's GitHub site<sup>5</sup>, and this shapefile was updated by the consultant team using the latest available aerials (dated late 2018) to reflect the most current conditions.

This updated shapefile was used to create a global area-weighted 10-foot blocked obstruction raster. The raster was then used to extract the percentage of area obstructed by buildings and assigned to area reduction factors (ARF) for each grid in each sub-model. The totally blocked grid element routine ("T Line") was not used to simplify file development. Totally blocked grids were rather assigned 1 in the partially blocked grid attribute (i.e., the IDG column). Similarly, to ease file development, width reduction factors (WRF) were not used in this study and were assigned a 0 value in the ARF.DAT file. The buildings that were modeled with the ARF functionality are shown in Figure 2-9.

<sup>&</sup>lt;sup>4</sup> https://blogs.bing.com/maps/2018-06/microsoft-releases-125-million-building-footprints-in-the-us-as-open-data

<sup>&</sup>lt;sup>5</sup> https://github.com/Microsoft/USBuildingFootprints

It should be noted that other flow obstructions, such as block walls, exist within the study area. One example is within the Dayton Valley Country Club, were substantial block wall exist. However, these walls were not modeled because they were not designed as engineered flood walls; and, as such, would not meet FEMA's criteria for a levee.

## 2.2.11 Model Adjustments

Manual cell elevation and Manning's n value adjustments were made in a few locations to better reflect physical conditions in the watershed. Both the elevation and n value adjustments are discussed in more detail below. All areas where the model was adjusted are shown in Figure 2-12.

## 2.2.11.1 Cell Elevations

The cell elevations that were adjusted fell into two main categories. These were:

- 1) Adjustments at culverts to obtain better hydraulics, and
- 2) Adjustment of the NEXTMap data to allow for better flow transfer off the LiDAR data to the NEXTMap data.

The adjustments at culverts occurred at three locations – the invert of the box culvert on Lakes Boulevard upstream of the airport was lower to show a more accurate elevation, the cell elevations that represent the roadway at the Ricci Road box culvert on Eldorado Canyon were adjusted to show the roadway elevation since the LiDAR data removed the roadway, and the cell elevations at the box culverts (discussed in Section 2.2.9.1.2) were lowered to represent the almost flat slope of the culverts.

The NEXTMap adjustment was only necessary where water flowed from the LiDAR data to the NEXTMap data. This situation only occurred in the flat area downstream of the mountains in the northwest area of the Upper model (shown in Figure 2-12). Other topography seam areas (between the LiDAR and NEXTMap) were handled by raising the NEXTMap data 10 feet to remove the potential for erroneous ponding.

### 2.2.11.2 Manning's n values

Areas, such as gravel mines or retention basins, that contain a large depth of ponded water can cause model runtimes to become extremely long due to excessive time step decrements. A relatively high Manning's n value is assigned to these areas to help alleviate this issue. The adjusted n value for deep ponded grid elements was chosen based on the recommended table of ponded n values shown as Table 2-8. However, a lower n value was generally used to ensure that the hydraulics weren't erroneously affected in some areas (e.g., at the Eldorado Canyon Dam).

For this study, the primary areas where n values were adjusted were:

- 1) The deep gravel mines along Eldorado Canyon (adjusted n value = 0.15),
- 2) The flood pool of Eldorado Canyon (adjusted n value = 0.08).
- 3) The lakes that function as retention basins within the golf course (adjusted n value = 0.08).

The cells where the elevations were adjusted to account for the removal of the box culverts also used an n value of 0.08.

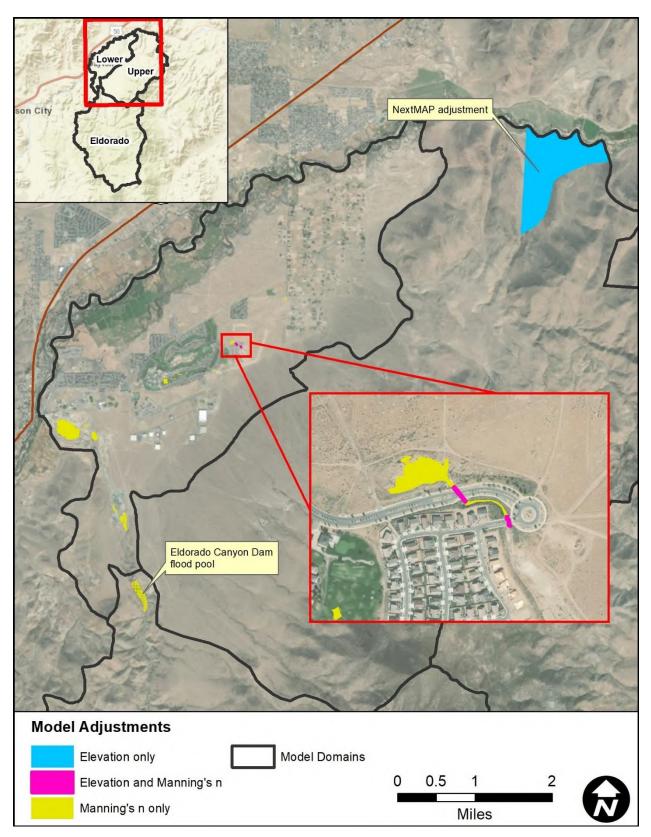

Figure 2-12. Locations and types of model adjustments

Depth (feet)	n value
5 - 8	0.08
8 - 10	0.10
10 - 15	0.20
> 15	0.30

Table 2-8. Recommended n values for deep ponded areas, from FCDMC (2016)

## 2.2.12 Model Control Parameters

CONT.DAT and TOLER.DAT contain numerical stability and simulation controls for the FLO-2D model. The CONT.DAT file controls simulation time, output report time interval, some numerical controls and model switches, such as infiltration and rain. The total simulation time was set to 15 hours for the 6-hour storm, while the total simulation time was set to 30 hours for the 24-hour storms. These times were sufficient to ensure that the bulk of the floodwave has traveled through the entire study area and keeping total model runtime reasonable (e.g., about 120 hours for the Lower model 100-year 24-hour simulation).

In the CONT.DAT file, the global Manning's n value adjustment factor (AMANN) and the limiting Froude number (FROUDL) were the numerical controls that were used in the South Dayton Valley ADMP study. For this study, these controls were set to:

- AMANN = 0 (depth integrated roughness is used with the SHALLOWN parameter)
- FROUDL = 1.5 (Off-site areas), 1.1 (detailed model area)
- SHALLOWN = 0.20 (Off-site areas), 0.15 (detailed model area)

For the limiting Froude number, a value of 1.5 was used in the off-site, upper watershed areas (Eldorado and Upper modeling domains) due to the presence of mountainous and piedmont areas where high flow velocities are possible since slopes can be greater than 20%. In the detailed model area, the limiting Froude number was set to 1.1 to account for the general reduction in slope in comparison to the higher slopes found in the upper watersheds. Similarly, the SHALLOWN was set to 0.20 for the upper watershed areas to account for the increased roughness due to large boulders and rocks, while the lower detailed model (Lower domain) used a value of 0.15. The relatively high SHALLOWN values were chosen due to the rocky terrain and surface cover that is found in the study watersheds (see Figure 2-8 and Figure 2-13).

The TOLER.DAT file contains the numerical tolerance settings specified for the model. These settings are: the flow exchange tolerance (TOL), percent allowed change in flow depth (DEPTOL), dynamic wave stability criteria (WAVEMAX), and Courant-Friedrich-Lewy numerical stability parameter for floodplain grid element flow exchange (COURANTFP). For the South Dayton Valley models, the settings applied were:

- TOL = 0.004 feet (the depth at which FLO-2D begins to route flow)
- DEPTOL = 0 (not used, model uses Courant number as stability criteria)
- WAVEMAX = 0 (not used, model uses Courant number as stability criteria)
- COURANTFP = 0.6 (main stability criterion used by FLO-2D)

These values have been used in similar studies, which yielded reasonable results. For this project, these values have produced good model stability and reasonable results.

Figure 2-13. Example of typical vegetation and rock cover in the upper piedmont areas

## 2.3 MODEL RESULTS

### 2.3.1 Floodplain Cross-Sections

Floodplain cross-sections were developed and included in the FPXSEC.DAT file to query flow hydrographs, peak discharges, and flow volumes from the FLO-2D model at key locations, such as:

- Major flow concentration locations,
- Areas near potential mitigation sites, and
- Areas of interest to Lyon County

Major floodplain cross-section locations are shown on Figure 2-14. Hydrograph plots at the floodplaincross-sections for each storm event are included in Appendix C. The peak flow and volume for each floodplain cross-section are shown in Table 2-9.

## 2.3.2 Depth and Discharge Results

Flow depth and discharge results from the existing conditions FLO-2D modeling are shown on Figure 2-15 through Figure 2-20. These figures are for general illustrative purposes and not practical for obtaining detailed information at site-specific locations. For more detailed information, please see the digital data in Appendix C, which includes the grid-based results for maximum flow depth, maximum peak discharge, maximum velocity, and other FLO-2D output.

#### 2.3.3 Animations

Google Earth animations of the Lower model have been included with the digital model results (see Appendix C). These animations are helpful for visualizing the dynamic nature of the flooding as it moves through the study area.

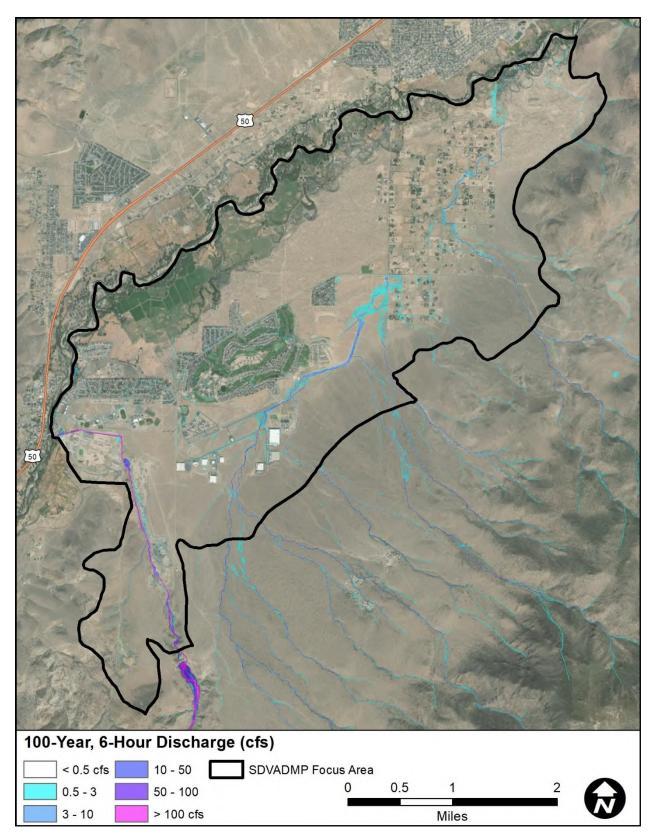

Figure 2-19. Existing conditions 100-year, 6-hour discharge results

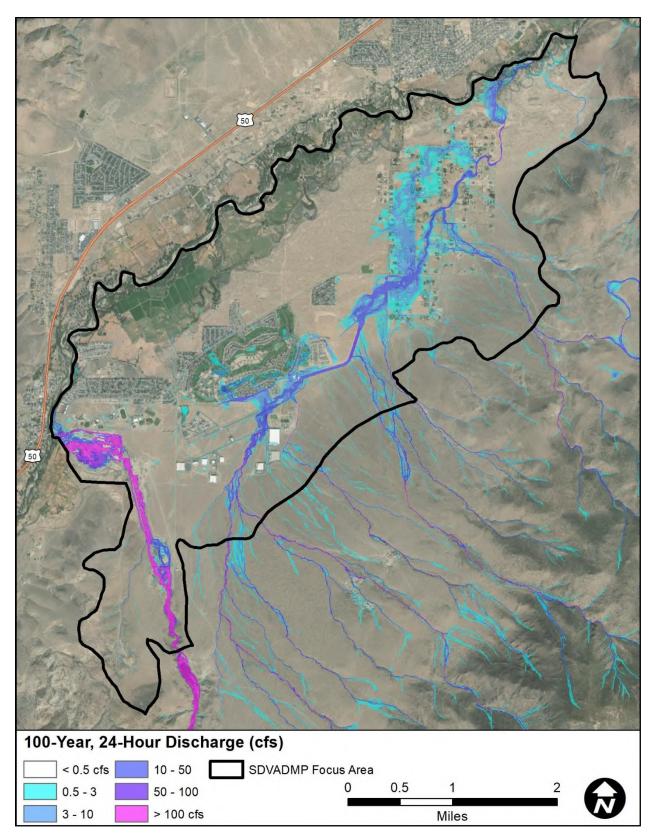

Figure 2-20. Existing conditions 100-year, 24-hour discharge results

## 2.4 VERIFICATION OF RESULTS

## 2.4.1 Comparison with USGS Regression Equations

As a verification of model results, the 100-year 6- and 24-hour results at seven drainage basins were compared with the 100-year USGS regression equation, shown as Equation (1), for the Eastern Sierras Region 5 (USGS, 1997).

$$Q_{100} = 7000 AREA^{0.782} (ELEV/1000)^{-2.18} (LAT - 28)^{4.6}$$
(1)

Where:

- *Q*<sub>100</sub> is the 100-year peak discharge (cfs)
- AREA is the drainage area (square miles)
- ELEV is mean basin elevation (ft)
- LAT is the latitude of site (decimal degrees)

The results from this comparison are shown in Table 2-10 and Figure 2-21, while the basin locations used for this comparison are shown in Figure 2-22.

Table 2-10shows both the 100-year 6-hour (labeled as 100Y6H) and the 100-year 24-hour (labeled as 100Y24H) peak flow results from the FLO-2D modeling compared with the 100-year flow from the regression equation. The unit discharges for each basin and the median values are also calculated and shown in the table.

The comparison indicates that the FLO-2D results for the entire study area are generally reasonable. In Figure 2-21, all results fall below the USGS envelope curve and within the cloud of values. However, 100-year 24-hour storm falls below the low- to middle-elevation study area line (which includes USGS Regression Regions 2-16, not just Region 5) for smaller drainage areas with the results from larger drainage areas rising above the line, while the results from the 100-year 6-hour storm fall below the line for all drainage areas.

When compared with the 100-year discharge relation for Region 5, the results are similar. The 100-year 24-hour storm follows the line for small drainage areas but diverges above the line as drainage area increases. Conversely, the 100-year 6-hour storm falls below the line at small drainage area and approaches the line as the drainage area increases. However, it should be noted that the USGS used mean values for variables other than drainage area when plotting this line. Therefore, this plot may not appear to fit the data.

Finally, since the 100-year 24-hour storm is the controlling storm, this comparison indicates that the FLO-2D results may be conservative (i.e., higher) for larger drainage basins (e.g., > 5 square miles), such as the Eldorado Canyon watershed (Basin ID: 1). However, the unit discharge comparison in Table 2-10 indicate the 100-year 24-hour median unit discharge are reasonable when compared with those generated from Equation (1). Additionally, the only basins that are larger than 5 square miles are contained within the Eldorado Canyon watershed, and that watercourse is contained within its channel as it flows through the focus area. Therefore, the results that impact the focus area of the SDADMP are reasonable Since the Eldorado Canyon watershed is a special case, it and the Eldorado Canyon Dam are discussed in more detail in Section 2.4.4

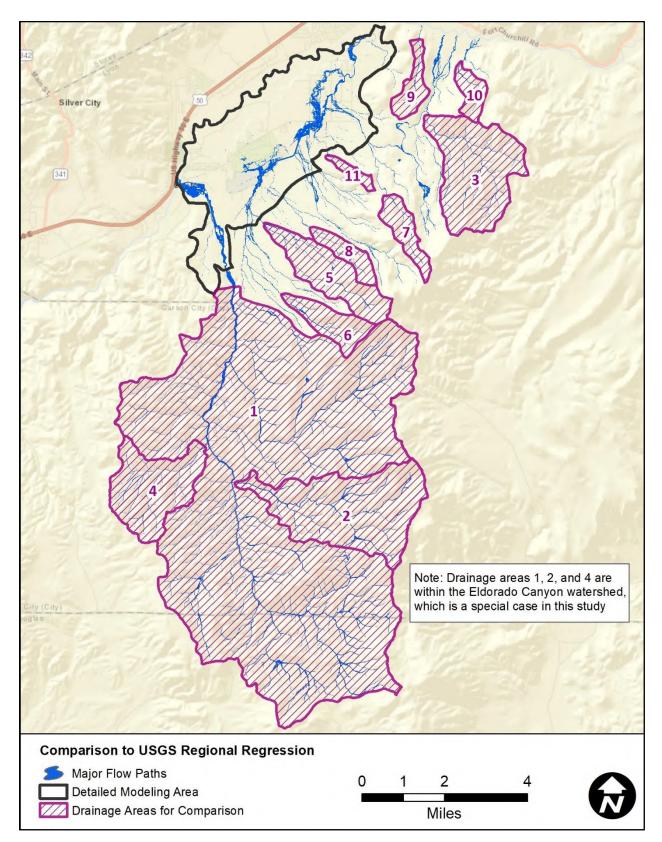

Figure 2-22. Drainage basins used for comparison of FLO-2D results to the USGS 100-year regression equations

#### 2.4.2 Additional USGS Data

As part of another hydrology update project, NDOT recently obtained peak flow estimates for both inactive and active crest stage sites. Since these were crest gages, they contained only peak flow estimates rather than entire hydrographs.

The maximum peak of record for each gage was parsed from the USGS data peak flow data, while the drainage area was collected from each gage's site description on the USGS website. However, not all gages listed the drainage area in the site description. Of the 216 total sites, forty-five did not list the drainage area, and these sites were excluded from the comparison to the SVADMP peak results. A summary of the drainage area statistics for all 216 sites is shown in Figure 2-23, and the spatial location of the sites is shown in Figure 2-24.

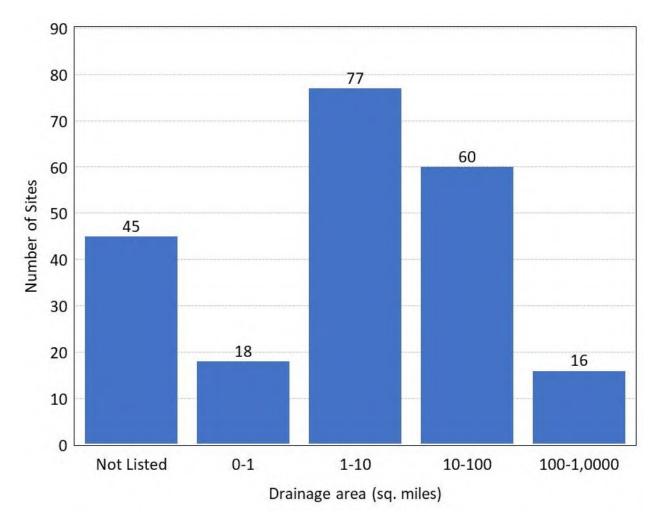

Figure 2-23. Drainage area statistics for USGS crest stage sites

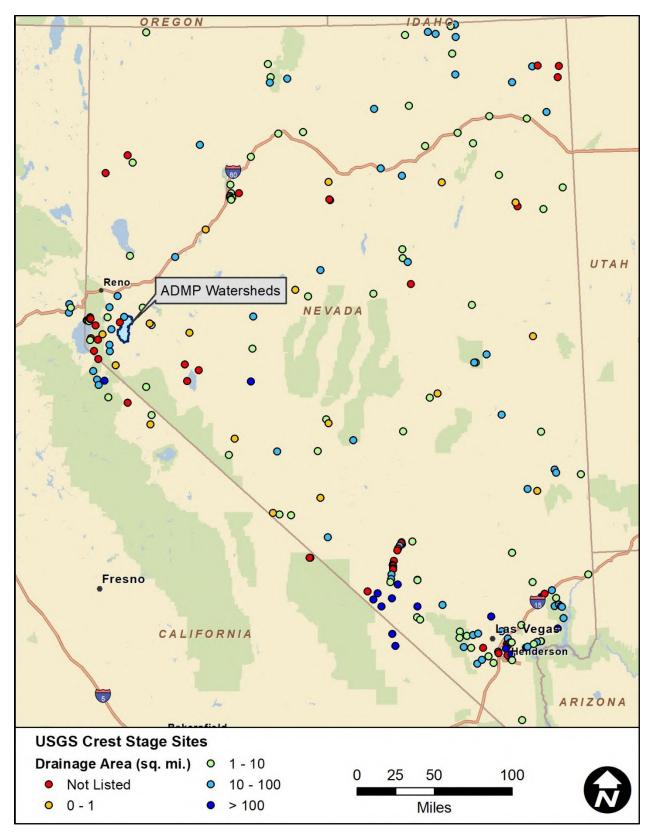

Figure 2-24. Location and drainage areas of USGS crest stage sites

As an additional verification of the peak flow estimates in the SDVADMP, the crest stage flow peak estimates were compared with the 100-year, 24-hour and 100-year, 6-hour FLO-2D results and peak flow estimates from the 1997 100-year regression equation (Equation 1). This comparison is shown as Figure 2-25. As before, both the FLO-2D and the 1997 100-year regression estimates fall within the cloud of data, which provides another indicator that the SDVADMP results are reasonable.

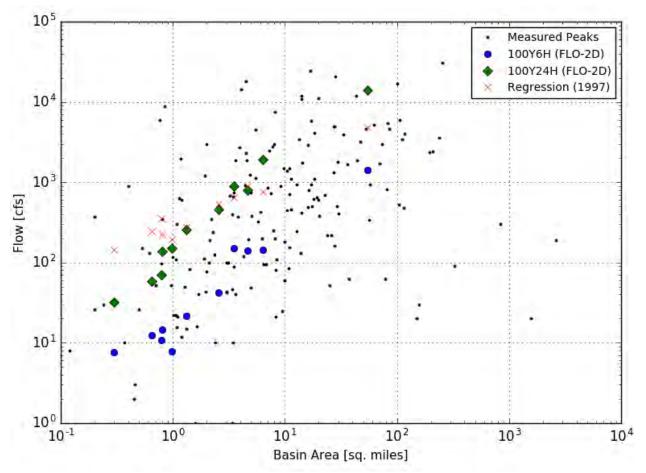

Figure 2-25. Comparison of FLO-2D results, 1997 100-year regression equation, and peak flow estimates from crest stage sites

#### 2.4.3 Historical Flooding Documentation

As a part of the public outreach effort, the consultant team collected photographs, videos, and anecdotal information of historical flooding from residents within the ADMP study area. This information was used to help verify and adjust the FLO-2D model if needed. In general, the model results corresponded well with the historical information. Information from four locations within the study area were submitted by residents. The four locations are listed below and are illustrated in Figure 2-26 through Figure 2-29 to show the correlation between model results and actual flooding accounts.

- 108 Rancho Road
- 130 Nugget Lane
- Near Gold Creek Drive and Dayton Valley Road
- Sutro Road south of Bonnie Court

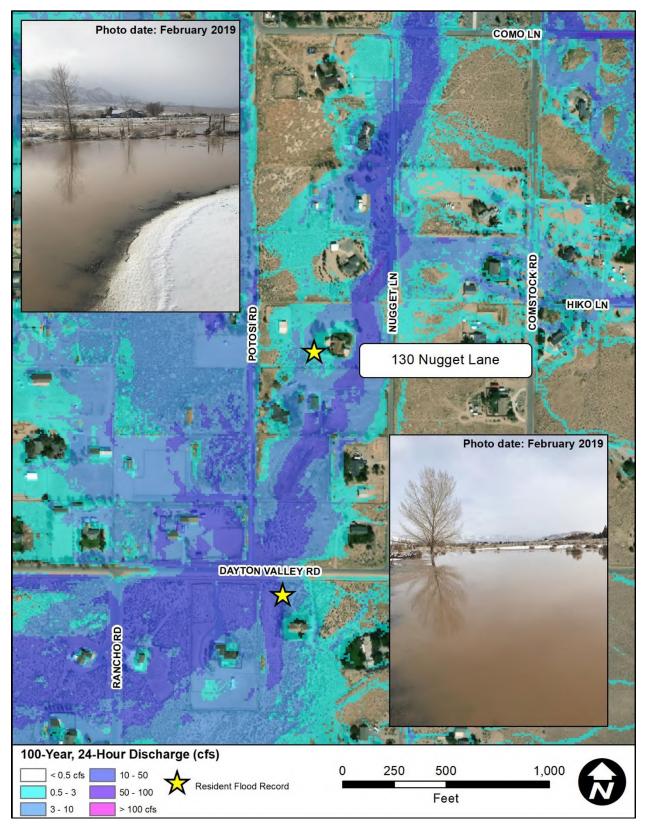

Figure 2-27. Verification for 130 Nugget Lane

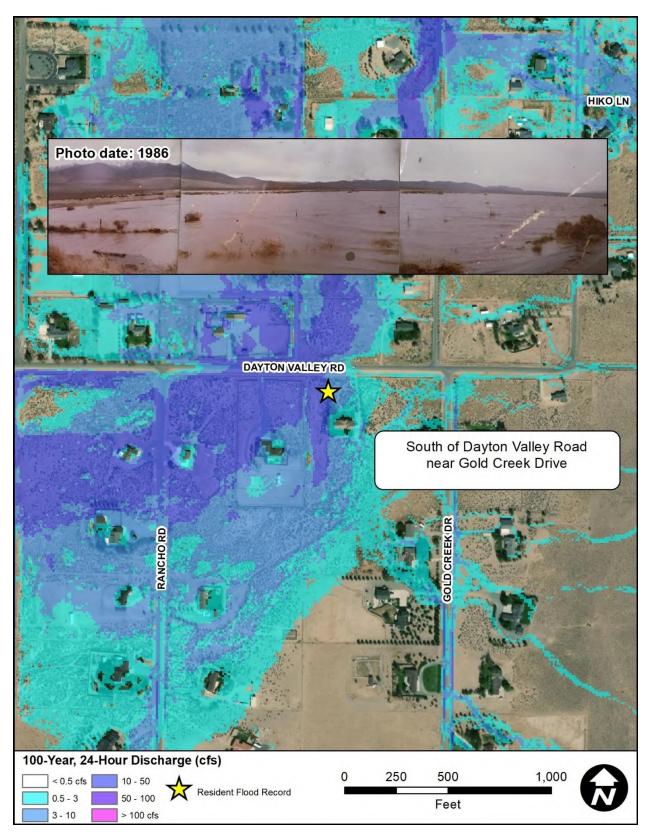

Figure 2-28. Verification for Dayton Valley Road near Gold Creek Drive

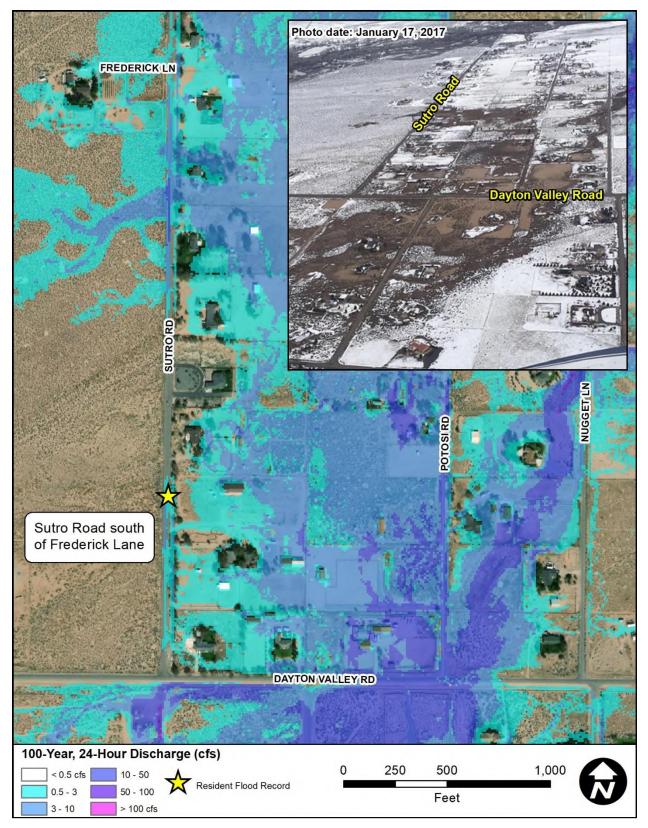

Figure 2-29. Verification for Sutro Road near Dayton Valley Road

#### 2.4.4 Eldorado Canyon Dam

The Eldorado Canyon Dam is a Bureau of Land Management (BLM) dam that was built in 1972 and modified in 1995 (USDI BLM, 2018) with a primary purpose of irrigation per the National Inventory of Dams<sup>6</sup>. Since this dam provides some control on the largest watercourse within the study area, the results in this area were reviewed in detail. In addition, the 100-year 24-hour peak flow rate from FLO-2D is 14,084 cfs upstream of the dam while the probable maximum flood (PMF) is 44,150 cfs, per the Nevada Division of Water Resources.

First, the current elevation-storage rating curve was computed from both the 2017 LiDAR data and the FLO-2D cell elevations (see Figure 2-30). This comparison gave confidence that the FLO-2D model approximated the correct storage volume based on the latest topographical information. However, the crest and spillway elevations show differences when compared with what is shown in the latest inspection report (USDI BLM, 2018). For example, the crest elevation is approximately 4705 feet (NAVD88) in the LiDAR data, while the minimum crest elevation per the inspection report is 4708.2 feet. Even though there is this elevation difference, no changes were made in the FLO-2D model because the elevations were derived from the latest USGS LiDAR data, which is the best, most comprehensive mapping in the vicinity of the Eldorado Canyon Dam flood pool. The FLO-2D cell elevations within the flood pool were derived only from the LiDAR data. Note that at the spillway elevation, the storage is approximately 85 ac-ft; while at the crest, storage is approximately 330 ac-ft. These volumes are much smaller than the 4500 ac-ft that is generated during the 100-year 24-hour event.

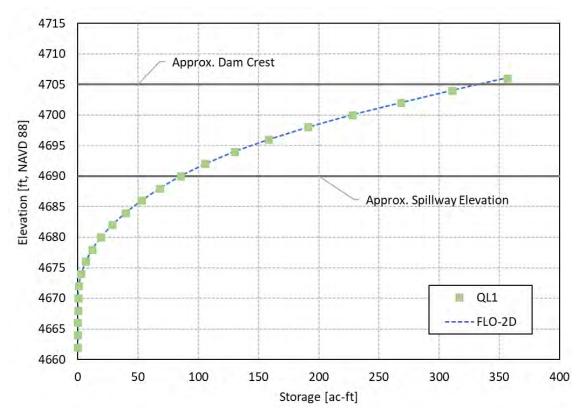

Figure 2-30. Current elevation-storage curves for Eldorado Canyon Dam based on USGS QL1 LiDAR and FLO-2D cell elevations

<sup>&</sup>lt;sup>6</sup> <u>https://nid.sec.usace.army.mil/ords/f?p=105:1:::::</u>

Second, an HEC-RAS 2D (RAS2D) model was developed to verify the FLO-2D results because the 100-year 24-hour event showed water overtopping the dam crest. Additionally, three FLO-2D scenarios (Base, Courant = 0.05, Limiting Froude = 3) were developed, and the results compared with the results from the RAS2D model. These scenarios were developed because with the base settings (i.e., those used in the SDVADMP) of FLO-2D the results are not directly comparable to RAS2D since FLO-2D has computational limiters, such as the limiting Froude number, and the numerical scheme is different. Similarly, FLO-2D also discretizes the physical surface differently than RAS2D. FLO-2D uses a regular square mesh (i.e., the grid size is constant and uniform in a single model), while RAS2D can use an irregular mesh with breaklines to enforce a cell boundary at a physical feature, such as a levee crest.

A comparison between the FLO-2D and RAS2D model results for the maximum water surface elevation (WSEL) sampled along a profile through the flood pool is shown in Figure 2-31. All FLO-2D scenarios produce essentially the same WSEL results, while RAS2D is consistently lower and does not show overtopping of the dam crest. However, all models showed that there was no attenuation during the 100-year 24-hour event. Approximately 14,000 cfs entered the flood pool and 14,000 cfs left. This is unsurprising considering the differences between the available storage volume and flood volume.

The differences in the WSEL results between models is likely due to differences in numerical scheme and discretization of the surface. A slightly higher n value was used in the FLO-2D model (0.08 in FLO-2D, 0.06 in RAS2D) because FLO-2D can become unstable when the depth is much larger than the cell size. In these scenarios, the maximum depth was greater than 35 feet, while the cell size is 20 feet.

Finally, the results from the FLO-2D modeling were acceptable for the SDVADMP for two principal reasons:

- 1) Eldorado Canyon Dam provides almost no attenuation to the 100-year 24-hour storm event (the controlling storm) in both the HEC-RAS and FLO-2D models.
- 2) The flow is contained within the main channel and gravel mines of Eldorado Canyon within the focus area of the study.

However, the hydraulics at the dam itself appear to be better resolved with the HEC-RAS model. This model is included in Appendix C.

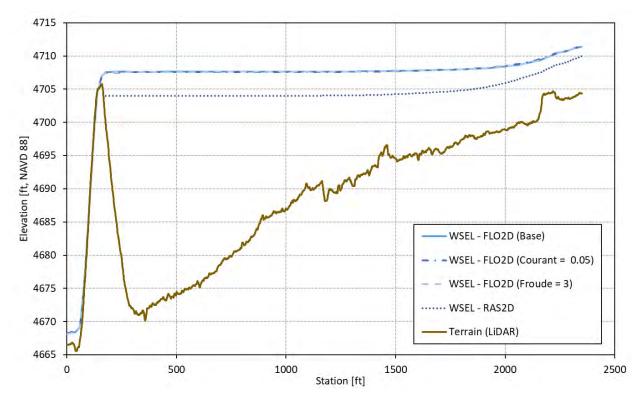

Figure 2-31. Comparison of FLO-2D and HEC-RAS maximum water surface elevations for the 100-year 24-hour event

## 2.5 SUMMARY

The existing conditions FLO-2D models were created using the best available information for land cover, land use, topography, and hydrology. Every effort was made to ensure the models represented existing conditions as of the date of the LiDAR survey and the NEXTMap data. However, the NEXTMap did not provide near the resolution of the LiDAR data, and areas along the LiDAR/NEXTMap seam were smoothed to prevent erroneous ponding. Therefore, flow patterns and peak discharges in areas within the NEXTMap limits should be verified before being used for future projects.

Photographs and anecdotal information collected from both Lyon County and the residents within the community were used to help calibrate and verify the modeling results. Like all models, the SDVADMP FLO-2D models are a simulation of potential conditions that could occur during a range of storm events. The models cannot exactly duplicate actual, observed storm events at all locations within the community due to the vast number of variables that change with each unique storm event.

The modeling results reflect the complex flooding and sedimentation hazards that exist within the South Dayton Valley study area. The results provide valuable, quantitative, detailed information from which future planning and development decisions can be based. The existing conditions models also serve as a foundation from which potential mitigation alternatives can be assessed (Section 5).

Although the ADMP FLO-2D modeling effort was not intended to replicate an actual historical flood event, the comparison of the modeling results with USGS regression equations, anecdotal flood information, and independent hydraulic calculations indicate the project FLO-2D models suitably depict

storm runoff conditions – indicating that the underlying input parameters are reasonable. Given the distributary nature of the flooding within the community, and the high sediment transport rates (see Section 5), flooding characteristics (e.g., depth, discharge, location) are likely to change from one flood event to the next. Even small anthropogenic changes to the landscape (e.g. dirt piles, berms, construction of outbuildings, landscaping debris piles, etc.) will result in sediment accumulation, channel scour, and changes in flowpath directions that may not be represented in the project FLO-2D modeling. In other words, the results of the modeling represent potential flooding conditions as of the date of the project topographic mapping. Updated mapping and FLO-2D modeling are recommended if major changes to the landscape occur in the future.

# **3** SEDIMENTATION ANALYSES

## 3.1 SEDIMENT SAMPLING AND TRANSPORT ANALYSIS

#### 3.1.1 Sediment Sampling

Since the SDVADMP study area has known sedimentation issues (see example of sediment deposition at a culvert in Figure 3-1), twelve sediment samples were collected in August 2019 by JEF staff to help classify the type of sediment being transported to (and through) the detailed model area. The sampling locations are shown along with the sample IDs in Figure 3-2. Due to the size of the sediment in some of the watercourses, nine of the twelve sediment samples were evaluated by the pebble count method (Wolman, 1954). The other three were processed via mechanical sieve procedures to compute the sediment gradation. The gradation curves from each of these samples are shown in Figure 3-3, while major characteristics of the sediment are tabulated in Table 3-1.

Table 3-1. Major characteristics of the sediment within the lower watershed

#### 3.1.2 Sediment Transport Analyses

The FLO-2D hydraulic modeling was used to assess the trends of both flooding and sedimentation throughout the study area. Hydraulic data from FLO-2D inherently includes both discharge and flow depth at each grid element. This hydraulic data was used to estimate sedimentation using the Yang sediment transport equation (1973, 1984) on a cell-by-cell scale. For this study, only the Yang equation was calculated based on the results of the analyses from the previous Dayton Valley ADMP. The median values from Table 3-1 were used in the sediment calculations.

For each modeled storm event, the total accumulated (i.e., throughout the entire storm event) sediment transport capacities were calculated at each cell. These accumulated capacities can identify areas where deposition or scour may be expected. The detailed results will be discussed in Section 3.2.

#### 3.1.2.1 Yang Equation

Sediment transport was calculated using the Yang sediment transport methodology. This approach followed the calculation outline found in the HEC-RAS Hydraulic Reference Manual (USACE, 2016). The grain size distribution was discretized into three equal mass components where sediment transport capacity was computed separately for each compartment and the results were combined while weighting the capacity of each compartment by its relative mass contribution. The governing equation for estimating sediment concentration for each grain size using the Yang approach is as follows:

$$\log C_t = 5.435 - 0.286 \log \frac{\omega d_m}{v} - 0.457 \log \frac{u_*}{\omega} + \left(1.799 - 0.409 \log \frac{\omega d_m}{v} = 0.314 \log \frac{u_*}{\omega}\right) \log \left(\frac{v_S}{\omega} - \frac{v_{cr}S}{\omega}\right)$$
(2)

 $\log C_t = 6.681 - 0.633 \log \frac{\omega d_m}{v} - 4.816 \log \frac{u_*}{\omega} + \left(2.874 - 0.305 \log \frac{\omega d_m}{v} = 0.282 \log \frac{u_*}{\omega}\right) \log \left(\frac{v_S}{\omega} - \frac{v_{cr}S}{\omega}\right)$ (3)

Where:

- *C<sub>t</sub>* is the total sediment concentration (ppm)
- $\omega$  is the particle fall velocity (ft/s)
- *d<sub>m</sub>* is the median particle diameter (ft)
- *v* is the kinematic viscosity (ft<sup>2</sup>/s)
- $u_*$  is the shear velocity (ft/s)
- V is the average channel velocity (ft/s)
- S is the energy gradient (ft/ft)

Equation (2) is used for sand with a median diameter < 2mm, while Equation (3) is for gravel with a median diameter is  $\ge 2mm$ . Within a model spanning 2-dimensions in plan-view, such as FLO-2D, the Yang methodology differentiates itself through application of vectorized parameters – average channel velocity and slope, notably. Using time-varying output from FLO-2D, the direction of maximum velocity at each time step was determined and the terms utilized in the Yang equation were applied in that direction. This method allows the sediment transport capacity analysis to adapt to changes in peak flow direction which is especially valuable in areas of flowpath uncertainty such as coalescing alluvial fans and areas subject to varied flooding sources.

# 3.2 RESULTS

# 3.2.1.1 Sediment Rasters

Since the total accumulated transport is calculated at each cell, an overall map of the study area with sediment transport capacities can be produced similar to the FLO-2D results presented in Section 3. Since the 100-year, 24-hour storm produces the largest amount of flow and sediment, it is used as a representative example. The relative total accumulated sediment transport within the focus area calculated with the Yang equation is shown in Figure 3-4. Note - The colors in both these figures represent relative transport capacity to each other, so green is relatively low compared to red, but green is higher than areas without color.

In general, the results are straightforward. Higher sediment transport rates appear in the channels, while lower rates appear as the flow spreads out over the piedmont. Unsurprisingly, the Eldorado Canyon produces the most sediment because it has the largest drainage area with the longest drain time. Finally, since these sediment results are based on hydraulic conditions, off-site inflows are considered because inflow hydrographs have been input at all major watercourses through the upstream FLO-2D modeling (see Figure 2-3).

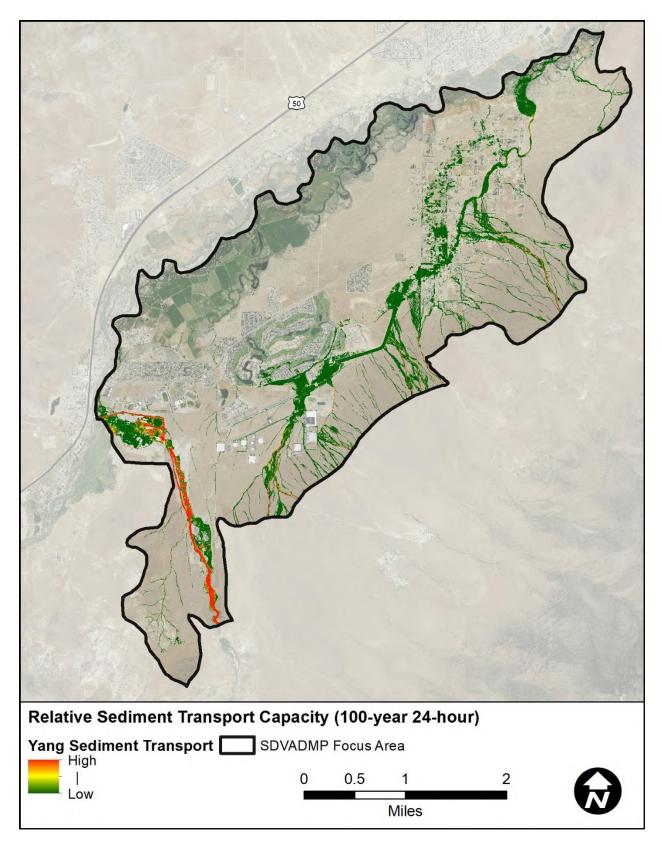

Figure 3-4. Total accumulated sediment transport capacity by the Yang methodology for the 100-year, 24-hour event

## 3.2.1.2 Sediment Profiles

A sediment transport profile was developed for the major overland flow path within SDVADMP focus area because alternatives will most likely be developed to control this overland flow. Conversely, since Eldorado Canyon is contained within its channel throughout the focus area and does not cause major flooding problems, a profile was not developed for this watercourse. As before, the 100-year 24-hour event is used as the representative example.

To develop these profiles, the total accumulated sediment transport through each station (or crosssection) over the entire storm event was calculated for the Yang equation. This transport profile was plotted and is shown in Figure 3-5.

In this study, these profiles were used in two ways. First, the profiles can be used to identify areas where sediment transport is not in equilibrium or out of balance. This is important because when the sediment transport is out of balance, erosion (degradation) or deposition (aggradation) is occurring within the wash. When sediment transport is increasing (i.e., the slope change is positive), the wash is gathering sediment through degradation. Conversely, when the sediment transport profile is decreasing, and the slope change is negative, the wash is losing sediment through aggradation.

Areas where there can be significant erosion or deposition are highlighted on the profile. The leftmost (or upstream) depositional area occurs where flow exits the confined mountain channels and distributes over a larger area on the piedmont. Below this area, sediment transport significantly decreases until the main flow path becomes confined again near station 5000. Downstream of station 5000, flow spreads out over an agricultural field where sediment transport decreases. These results are consistent with what would be expected given those hydraulic conditions.

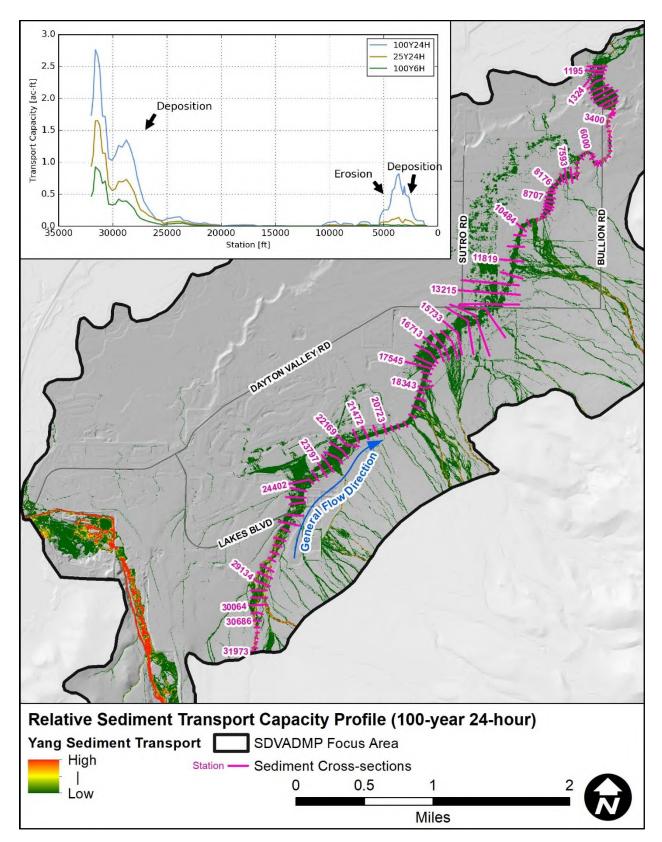

Figure 3-5. Cumulative sediment transport profile for the primary overland flow path throughout the 100-year 24-hour event

# 4 FLOOD HAZARD CLASSIFICATION

# 4.1 PURPOSE

During a severe storm event, flood waters flow throughout the South Dayton Valley ADMP study watershed. However, not all flood hazards pose a risk to people or to their properties. Flood risk depends on the presence of both a flood hazard and a person (or their property). As an example, flow in a constructed flood control channel does not present a risk until someone enters the channel. Identifying areas where flood waters may cause risks that potentially harm people (or property) is an important objective of the ADMP. Identification of potential flood risks in the study area helps the consultant team prioritize which flood problems should be addressed and in what order.

For the purposes of this study, flood hazards were defined based on the physical characteristics of the flood water – that is, the location, depth, and velocity associated with those flood waters. The hydrology and hydraulic modeling results were used to define flood hazards for three storms:

- The 25-year, 24-hour event,
- The 100-year, 24-hour event, and
- The 100-year, 6-hour event.

The flood risk assessment involved selecting criteria and quantifying flood risks throughout the study watershed using the FLO-2D model results. Three types of potential flood risks were assessed – flooding risks to pedestrians, passenger vehicles, and structures.

In addition to the flooding risks, two other types of flood consequence assessments were conducted:

- Building Inundation Assessment, and
- HAZUS Event-Based Analysis.

The building inundation and HAZUS assessments are planning level analyses to estimate the number of habitable structures and associated damage costs by flow depths greater than six inches. Since this analysis will be done for both the base (i.e., existing) and the with-alternatives conditions (see Section 5), it gives a quantitative estimate of the effectiveness of the potential alternative structures. Both analyses were performed for all three storm events.

The following sections describe the flood classification criteria, methodology, and description of provided electronic files for each potential flooding assessment.

# 4.2 FLOODING HAZARDS TO PEDESTRIANS

Pedestrian flood hazards were classified using the depth-velocity relationship outlined in the United States Bureau of Reclamation (USBR) Technical Memorandum 11 (TM 11) (1988). The depth-velocity relationships presented in TM 11 are a good basis for flood hazard classification since the criteria are widely accepted. TM 11 presents two possible classifications for pedestrians; flood danger levels for adults and for children. It was decided to use the flood danger classification for children throughout the entire watershed to simplify the methodology and to be conservative. The depth-velocity flood danger level relationship from TM 11 is shown as Figure 4-1.

The following three categories exist for pedestrian flood hazards:

- Low: These are areas with depths and velocities corresponding to the Low Danger Zone as shown in Figure 4-1. Low pedestrian hazards are not displayed on the map exhibits because, per TM11, low hazard zones do not present a threat to children of almost any size (excluding infants) and cover all areas not classified with a higher flood hazard.
- *Moderate*: Areas with depths and velocities corresponding to the Judgment Zone in Figure 4-1 have been labeled as having a moderate potential flood hazard to pedestrians.
- *High*: Areas with depths and velocities corresponding to the High Danger Zone in Figure 4-1 have been labeled as having a high potential flood hazard to pedestrians.

The flood hazards to pedestrians have been digitized in GIS in the form of a raster. The rasters generated for the risk analysis coincide with the FLO-2D grid elements with a 10-foot by 10-foot pixel size. The raster contains values of 1, 2, and 3 which correlates to a low, moderate, and high hazard classification, respectively. Since the 100-year, 24-hour storm produces the largest peak runoff for most areas (see Table 2-9), the flooding hazard from this storm event is shown as Figure 4-2.

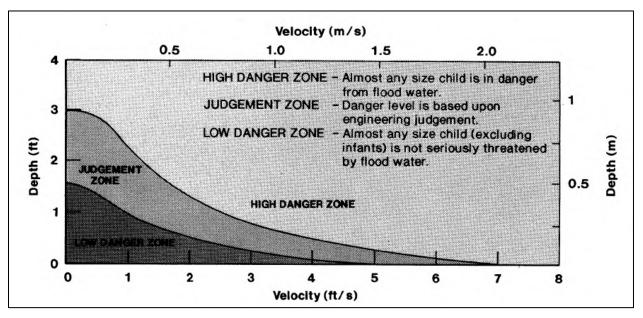

Figure 4-1. Depth-Velocity flood danger level relationship for children, from USBR (1988)

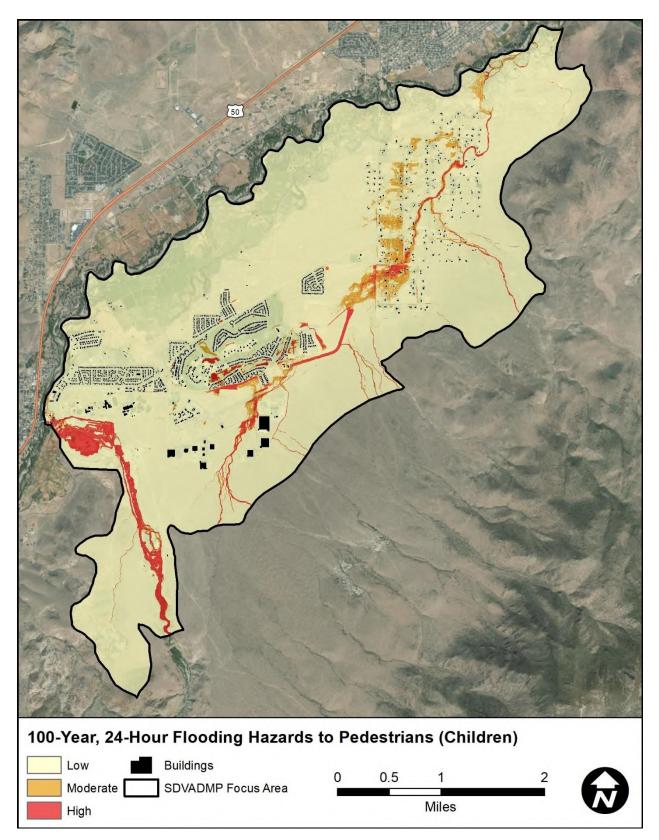

Figure 4-2. USBR criteria flooding hazards to pedestrians based on the 100-year, 24-hour results

# 4.3 FLOODING HAZARDS TO PASSENGER VEHICLES

Potential hazards to passenger vehicles were classified using a combination of minimum depth criteria and the depth-velocity relationship in TM 11 as shown in Figure 4-3. The following four categories exist for passenger vehicle flood hazards:

- Low: This hazard category is based solely on minimum depth criteria and is for roadway crossings with depths less than half a foot. Low passenger vehicle hazards are not displayed on the map exhibits because low hazard zones indicate areas where vehicles "are not seriously in danger" and, as such, almost any size passenger vehicle can safely pass. Also, this hazard classification covers all areas not classified with a higher flood hazard. This classification is not explicitly shown in the Figure 4-3.
- *Moderate*: This hazard category is based on a combination of minimum depth criteria and the depth-velocity relationship in TM 11. Specifically, these are roadway crossings with depths and velocities falling into the Low Danger Zone (as shown in Figure 4-3) that also have greater than a half a foot of depth. The threshold depth of half a foot was chosen because half a foot of water will reach the bottom of most passenger cars and can cause loss of control and possible stalling.
- *High*: Roadway crossings with depths and velocities corresponding to the Judgment Zone in have been labeled as having a high potential flood hazard for passenger vehicles.
- *Very High*: Roadway crossings with depths and velocities corresponding to the High Danger Zone in Figure 4-3 have been labeled as having a very high potential flood hazard for passenger vehicles.

The flood hazards to passenger vehicles have also been digitized in GIS in the form of a raster. The raster contains values of 1, 2, 3, and 4. These values correlate to low, moderate, high, and very high classification, respectively. The TM 11 flooding hazards to vehicles for the 100-year, 24-hour storm is shown in Figure 4-4.

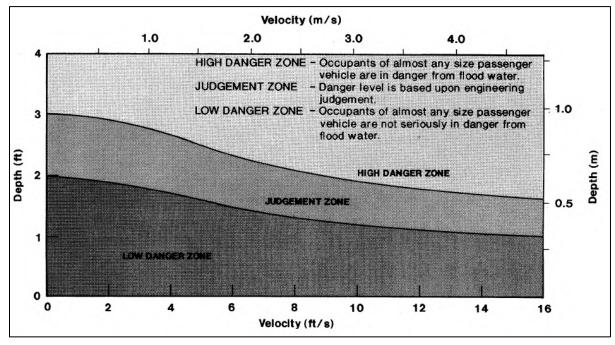

Figure 4-3. Depth-Velocity flood danger level relationship for passenger vehicles, from USBR (1988)

To isolate the actual risk to vehicles, the street centerlines GIS layer was intersected with the hazards zones to produce a "Potential Risk to Passenger Vehicles" map. This isolates the road crossings that pose a risk to vehicles during a storm event. Only the 100-year 24-hour and the 25-year 24-hour storm produce conditions of "High" risk using the USBR criteria. There were no locations of "Very High" risk from any of the three storm events modeled. The "High" risk road crossing locations for the 100-year, 24-hour and 24-year, 24-hour storms are shown in Figure 4-5 and Figure 4-6, respectively.

During the two storm events there are eleven (11) distinct crossing areas with a "High" hazard classification which are numbered below and shown in Figure 4-5 and Figure 4-6.

#### <u>Rancho Area</u>

- 1. Como Lane between Comstock Road and Imperial Road
- 2. Imperial Road and Ione Lane
- 3. Nugget Lane between Hiko Lane and Como Lane
- 4. Nugget Lane between Hiko Lane and Como Lane
- 5. Ophir Road between Ione Lane and Eureka Lane
- 6. Potosi Road between Dayton Valley Road and Hiko Lane
- 7. Potosi Road and Dayton Valley Road
- 8. Sutro Road between Dayton Valley Road and Frederick Lane

#### Dayton Valley Golf Course Area

- 9. Grayhawk Drive between Grayhawk Court and Lythm Court
- 10. Grayhawk Drive and Lythm Court
- 11. Lakeview Drive north of Moore Avenue

# 4.4 FLOODING HAZARDS TO STRUCTURES

Potential hazards to buildings were classified using the depth-velocity relationship from TM 11. The depth-velocity relationship from TM 11 is shown as Figure 4-7. The following three categories exist for potential flood hazards to structures:

- *Low*: Buildings that have contact with at least one FLO-2D grid element that has a depth-velocity relationship corresponding to the low danger zone in Figure 4-7 have been designated as having a low potential flood hazard.
- *Moderate*: Buildings that have contact with at least one FLO-2D grid element that has a depthvelocity relationship corresponding to the judgment danger zone in Figure 4-7 have been designated as having a moderate potential flood hazard.
- *High*: Buildings that have contact with at least one FLO-2D grid element that has a depth-velocity relationship corresponding to the high danger zone in Figure 4-7 have been designated as having a high potential flood hazard.

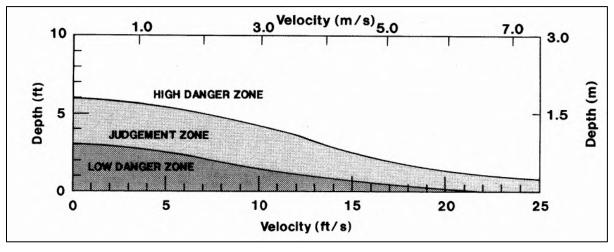

Figure 4-7. Depth-Velocity flood danger level relationship for structures built on foundations, from USBR (1988)

To create the building flood hazard classification, the building polygon shapefile is intersected with the flood hazard layer using GIS software tools. When multiple grid cells from the flood hazard layer intersect one building polygon, the maximum hazard classification is assigned to the building. Buildings with less than 600 square feet (e.g., unattached garages or sheds) were not considered because they were assumed to be uninhabited due to their size. The result is a building polygon shapefile with a hazard attribute classifying low, moderate, or high flood hazards.

The tabulated building hazard results are shown in Table 4-1. Due to the relatively shallow flooding in the project area, there are no buildings with a high or moderate hazard classification based on the TM 11 criteria. The 100-year 24-hour flooding hazards to buildings raster is shown in Figure 4-8.

Base Conditions				
Recurrence	<b>Building Count</b>	<b>Building Count</b>	<b>Building Count</b>	Total Building
Interval	Low	Moderate	High	Count
25Y24H	2,105	1	0	2,106
100Y24H	2,105	1	0	2,106
100Y6H	2,106	0	0	2,106

Table 4-1. Building flooding hazard classification results

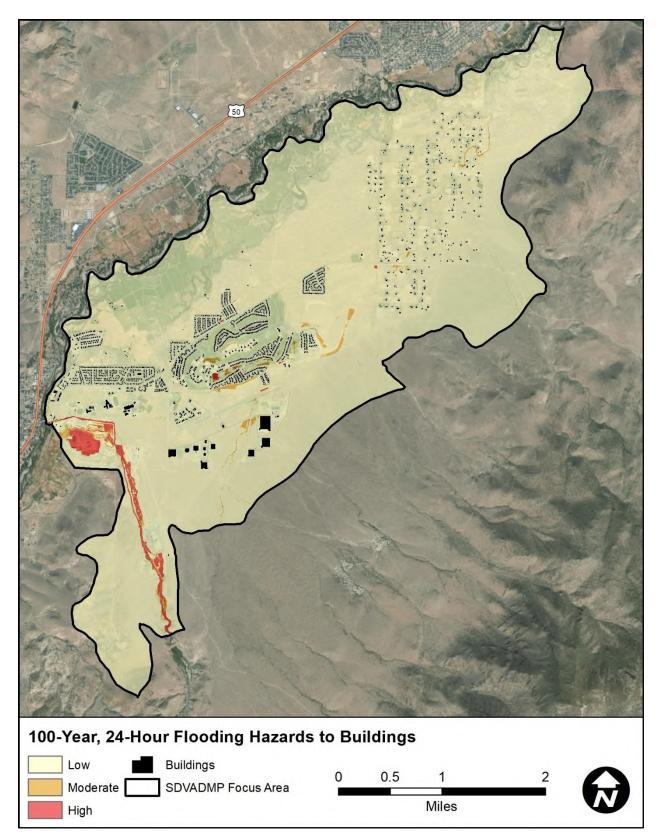

Figure 4-8. USBR criteria flooding hazards to buildings based on the 100-year, 24-hour results

# 4.5 BUILDING INUNDATION ASSESSMENT

## 4.5.1 Methodology

The USBR TM 11 procedures are commonly used within the engineering community for assessing flood risk. However, TM 11 was developed for conditions downstream of a dam failure. As such, lower flood depths may produce a "Low" risk classification for buildings with TM 11 but may be of a sufficient depth to justify a higher risk classification. To both verify the TM 11 results and to provide a lower threshold risk assessment, a separate building impact analysis was run using the building footprint data and the maximum depth results from the FLO-2D modeling for the base conditions. The maximum depth layers only consider the maximum depth that occurred during the model simulation.

From the building footprint data, there are 2,150 structures within the HAZUS study area; however, not all these structures are habitable structures (e.g. - water tanks or sheds). For this analysis, the same 600 square foot filter that was used in the "flooding hazard to structures" analysis (see Section 4.4) was applied. After applying this filter, there are 2,106 structures in the study area.

In this section, the documentation will focus on the base conditions analyses, while the with-alternatives results will be presented later in Section 5.

#### 4.5.2 Base Conditions

Each building was classified based on the maximum depth that fell within the structure outline. The structures were tabulated into four groups:

- 1)  $0.25 \text{ ft} < \text{Depth}(h) \le 0.5 \text{ ft} \text{Low}$
- 2) 0.5 ft  $\leq$  Depth (h)  $\leq$  1.0 ft Moderate
- 3) 1.0 ft < Depth (h) High
- 4) 0.25 ft < Depth (h) (inclusive of groups 1 through 3 above)

The results for existing conditions are tabulated in Table 4-2, while the results for the 100-year 24-hour storm are shown in Figure 4-9.

Base Conditions					
Recurrence	Building Count Flow Depth	Building Count Flow Depth	Building Count Flow Depth	Total Building Count	
Interval	0.25' < h ≤ 0.5'	0.5'< h ≤ 1'	1' < h	0.25' < h

# 4.6 HAZUS ANALYSES

## 4.6.1 Methodology and Purpose

FEMA's HAZUS program<sup>7</sup> is a standardized computer software package that automates FEMA's methodology for estimating potential economic losses and human displacement due to natural disasters such as earthquakes, floods and hurricanes. For flood related losses, HAZUS has the capability to perform varying levels of analyses that are distinguished primarily on the amount of user provided data. A Level 1 analysis is primarily based on generalized data provided with the software and rudimentary estimations of hydrology and flood depths to estimate flood risk. A Level 2 analysis blends user generated data with software data. A Level 3 analysis primarily uses all user generated input data. The analysis performed in this study would be considered a simple Level 2 since more detailed flood risk data (flood depth grids from FLO-2D) has been generated external to the model and imported for use in conducting the loss analyses.

In HAZUS, the flood depth grids are analyzed against a general building stock (GBS) database that is spatially tied to the 2010 Census blocks. The HAZUS analysis also considers single location essential facilities (e.g. – fire stations, hospitals, etc.). Both data sets contain attributes that represent an estimate of the number of buildings, building type, population, building replacement costs and so forth. However, the GBS data are generalized to the level of a census block. Since these estimates are based on the resolution of census blocks, the loss estimates are considered valid for a planning level of analysis. For a more complete explanation of the HAZUS modeling package, see the link provided in the footnote below.

Flood hazard loss estimates for the base and with-project conditions were calculated for the SDVADMP study using HAZUS 4.2 with the Service Pack 01 (SP01) update. In the 4.2 release of HAZUS, an erroneous multiplier was removed from the business interruption calculations that will significantly increase the economic losses from business interruptions. This correction should be recognized when comparing results from older versions of HAZUS. Additionally, the state databases were updated with 2018 valuations with the SP01 update. However, for this study, the business interruption estimates were not included because they were estimated in the hundreds of millions of dollars; and, as such, completely overwhelmed the direct building losses.

The purpose of the HAZUS analyses is to quantify the economic benefit from reduced flood damages that may be realized with the construction of all or part of the alternatives. The HAZUS default damage curves were used for all types of structures, with two exceptions. The United States Army Corps of Engineers (USACE) New Orleans District depth-damage curve (ID 143) was used for one story slab foundation residential structures, while the USACE New Orleans depth-damage curve (ID 57) was used for the contents of those same structures. With these curves, more reasonable estimates of the economic damages were calculated.

As before, the documentation in this section will focus on the base conditions analyses, while the withproject results will be presented after the alternatives are discussed. The two scenarios will be compared in that section.

<sup>&</sup>lt;sup>7</sup> HAZUS-MH 4.2 (https://msc.fema.gov/portal/resources/hazus)

#### 4.6.2 Base Conditions

These estimates only include direct building loss. According to HAZUS literature (FEMA, 2015), "the direct building losses are the estimated costs to repair or replace the damage caused to the building and its contents." In these tables, the total property column includes residential, commercial, industrial and miscellaneous other structures. Therefore, the total property represents the sum of other four categories. Finally, all estimates are based on the HAZUS GBS database, which is tied to 2010 census data and 2018 dollars.

A results summary is presented as Table 4-3. From these results, the 100-year 24-hour storm event causes significantly more damage than the other storms. Based on the results, the 25-year 24-hour event causes slightly more damage than the 100-year 6-hour storm, which is surprising but not unreasonable given the magnitudes of the precipitation in this region (see Table 2-3). These results show the same general trends as the Dayton Valley ADMP. However, the 100-year 6-hour results are much lower on relative basis than in that study. The differences in magnitude between the South Dayton Valley and Dayton Valley results are most likely due to the size difference between focus areas (13.5 square miles SDVADMP versus 18.3 square miles for the DVADMP) and the location, type, and density of development.

Base Conditions					
	Direct Building Economic Loss

1. May not be a	1. May not be additive due to rounding in internal HAZUS calculations				

# 4.7 SUMMARY

In this section, the methodologies and results from five separate hazard assessments were presented. These included:

- Flood hazards to children
- Flood hazards to vehicles
- Flood hazards to buildings
- Building inundation assessment
- HAZUS analyses

These analyses help identify areas that have a higher risk of flooding and which property and infrastructure are most susceptible to damage. Having this information helps focus the mitigation alternative to areas where they are most needed. Additionally, the last two analyses (the building inundation assessment and the HAZUS analysis) help show if the proposed alternatives are reasonable and cost-effective. The HAZUS analysis is a standard FEMA methodology for estimating potential economic losses.

# 5 REGIONAL FLOOD MITIGATION ALTERNATIVES

# 5.1 INTRODUCTION

The development of the regional alternatives comprised the following elements:

- 1) Drainage improvement assessment for the Ranchos area
- 2) Flood hazard identification
- 3) Alternative formulation/evaluation
- 4) Development of conceptual 15% design plans and cost estimates for the selected mitigation alternative

JE Fuller (JEF) served as the lead on the flood hazard identification and alternative formulations with assistance from Lumos and Associates (Lumos), who were the lead in the development of the 15% design plans and cost estimates for the selected mitigation alternative. Figure 5-1 summarizes the process for developing the regional alternatives.

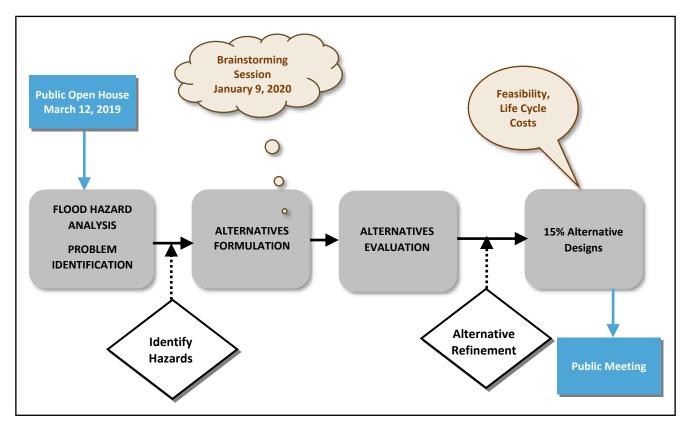

Figure 5-1. Development process for the regional flood mitigation alternatives for the ADMP

# 5.2 MITIGATION ALTERNATIVES

On January 9, 2020, the consultant team (JEF and Lumos) conducted a brainstorming session to develop initial mitigation concepts and verify their feasibility. The meeting resulted in the conceptualization of several regional mitigation systems. On January 21, 2020, the consultant team met with the client team to present and discuss the mitigation system options. The system options were comprised of the following structure elements:

- Detention basins
- Collector channels
- Conveyance channels
- Culverts
- Existing channel improvements
- Existing detention basin improvements

Through the Alternatives Formulation and Alternatives Evaluation process, the consultant team developed three mitigation alternative systems that were presented to Lyon County. Each system was comprised of a series of sediment/detention basins and collector/conveyance channels in various configurations that would result in significant mitigation of offsite flooding to the South Dayton community. Each alternative system is described in the following sections and summarized in Table 5-1.

# 5.2.1 Alternative 1

Alternative 1 was initially proposed as six sediment/detention basins located at the major offsite drainage channels on the lower piedmont. The basins would be connected to a collector/conveyance channel that spanned the entire length of the piedmont and drained to the Carson River east of the South Dayton community (Figure 5-2).

# 5.2.2 Alternative 1a

Alternative 1a is comprised of five sediment/detention basins, a series of collector/conveyance channels, and proposed improvements to existing drainage infrastructure (Figure 5-3). Three basins would be located south of the airport commercial district and would collect and pass offsite runoff to a conveyance channel that would flow to the northwest and empty into the main channel of El Dorado Canyon. A separate collector channel would be constructed southeast of the airport commercial district and would be incorporated into the existing drainage channel to the east of the commercial district. The existing channel would need to be improved to collect and convey the storm runoff. A new conveyance channel would need to extend from the existing channel to the existing regional detention basin east of the Dayton Valley Golf Course community. The existing basin would also need to be improved to safely detain and convey the storm runoff. A new conveyance channel would extend from the existing basin outlet across Dayton Valley Road and north to the Carson River.

To mitigate offsite flows from east of the Ranchos area, a single sediment/detention basin would be located on the main drainage corridor and would connect to a collector/conveyance channel that would extend directly north and connect to the existing channel that exists the Ranchos development. The existing channel would require improvements to convey the storm runoff directly north to the Carson River.

#### 5.2.3 Alternative 1b

Alternative 1b incorporates all the structure elements of 1a except for the conveyance system downstream of the existing regional basin. The 1b system includes a conveyance channel from the basin outlet to Dayton Valley Road, then extends south of the road to the existing drainage channel that flows through the Ranchos development (Figure 5-4). A new culvert at Dayton Valley Road would allow the flow to pass beneath the road to the existing channel. The ADMP hydraulic modeling results indicate a section of the existing channel does not have capacity to convey the offsite flow, thus channel improvements would be necessary. The existing channel alignment through the Ranchos intersects many individual private parcels.

## 5.2.4 Summary

Figure 5-2 through Figure 5-4 illustrate the conceptual layout of each alternative system. Land ownership within the alternative areas is either Private or Bureau of Land Management (BLM). The land ownership boundaries are shown in the figures.

Table 5-1 provides a summary of the alternatives and the key opportunities and constraints that were presented to Lyon County to aid in their decision in selecting a preferred alternative system to advance to the conceptual design phase of the ADMP.

Alternative System	Structure Elements	Opportunities	Constraints	Preliminary Cost Estimates
1	<ul> <li>New Sediment/Detention Basins</li> <li>New Collector/Conveyance Channel</li> </ul>	<ul> <li>Regional mitigation solution</li> <li>Minimal private land right-of-way acquisition needed</li> <li>Construction/design with regional future bypass road could result in significant cost savings</li> </ul>	<ul> <li>Coordination with BLM</li> <li>Coordination and approval needed from 6 private parcel owners</li> </ul>	25-yr: \$28.2 million 100-yr: \$44.0 million

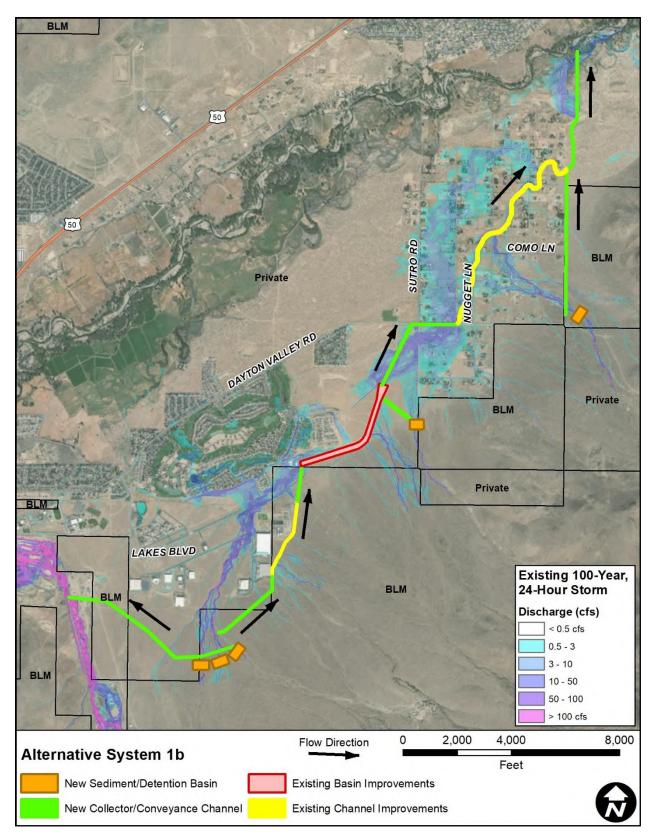

Figure 5-4. Conceptual layout of Alternative 1b

# 5.3 SELECTED REGIONAL MITIGATION ALTERNATIVE

Lyon County selected Alternative System 1 to advance to the concept phase of the ADMP. The final system concept is comprised of six sediment/detention basins and one collector/conveyance channel that spans the length of most of the Pine Nut Mountain piedmont that drains to South Dayton (Figure 5-5). The consultant team developed proposed mitigation structures for both the 100-year and 25-year storms to assess which would provide the most overall benefit. There were many considerations that led to the selection of the alternative system. A few of the most significant are:

- Provides a regional solution that mitigates most of the offsite flood risk to the South Dayton community.
- The Lyon County Comprehensive Master Plan<sup>8</sup> includes a proposed South Dayton Bypass Road that could parallel the proposed conveyance channel, resulting in significant cost savings if constructed concurrently with mitigation system; or at least each project is designed and constructed with the other project in mind.
- The basins and channel are located primarily on public land which would minimize the number of private landowners involved in acquiring property right-of-way to construct and maintain the system.

<sup>&</sup>lt;sup>8</sup> https://www.lyon-county.org/773/Comprehensive-Master-Plan

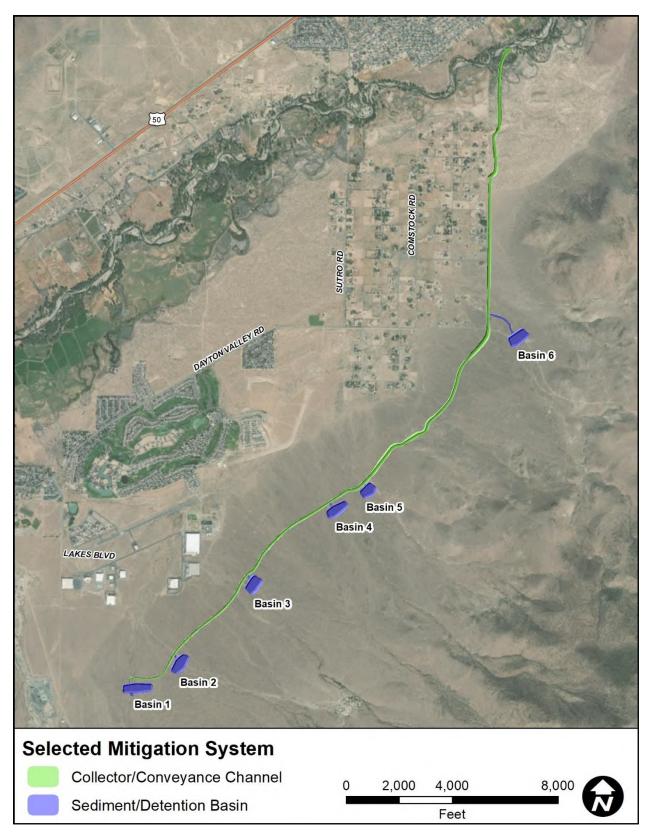

Figure 5-5. Selected mitigation system

# 5.3.1.1 Sediment Considerations for Proposed Alternatives

The primary function of the proposed basins is to trap sediment to prevent the conveyance channel from depositing sediment that is presently distributed across the piedmont to one outlet point on the Carson River.

An estimate of sediment delivery volumes is beneficial when assessing proposed infrastructure locations and designs. Unlike scour, long-term sediment deposition is a common issue for infrastructure and often cannot be mitigated through on-site improvements. Common examples of sediment deposition challenges for infrastructure include culvert sedimentation and loss of storage volume in detention basins due to deposition. To assist in the design of proposed infrastructure improvements, sediment yield was calculated for the contributing watersheds.

Sediment transport capacity calculations were performed as described previously in Section 3 with the Yang method. Sediment transport capacity rates were integrated over time at pre-defined FLO-2D floodplain cross-section locations to calculate total sediment transport volumes at each cross-section for the suite of storms modeled. Sediment transport volumes per storm were then probabilistically composited based upon likelihood of occurrence within a 100-year span following guidance outlined in SLA (1985) with the following relationship:

annual probabilistic value =  $0.4 * (2 \cdot year value) + 0.2 * (5 \cdot year value) + 0.08 * (10 \cdot year value) + 0.04 * (25 \cdot year value) + 0.015 * (100 \cdot year value) + 0.002 * (500 \cdot year value)$ (4)

Equation (4) calculates an annualized average value based upon a non-continuous storm recurrence range for commonly analyzed storm frequencies.

Yang sediment transport equations yield results in concentration as parts per million (ppm). The maximum concentrations per grid were converted from a mass per volume result to a volume per volume relationship to determine the maximum sediment concentrations for flow bulking due to sediment. Flow bulking is a useful method for accounting for extra flood volume due to entrained sediment in flood flows.

The Yang sediment transport estimates were used in the development of the 15% design alternatives. Three times the annual sediment transport volume plus one design event (100-year or 25-year) sediment transport volume was used as the total sediment volume for each basin. The total sediment design volumes for the proposed flood mitigation basins are summarized in Table 5-2.

Finally, it should be noted that sediment throughput calculations exhibit wide variability based on the transport equation used, grain size of the sediment, watershed slope, and many other variables. Similarly, since the hydraulic calculations are the backbone of any sediment calculation, infiltration volumes and Manning's n values also affect total sediment volumes. Therefore, most analyses in this study were taken on a relative basis – that is the absolute values are not precise. However, the sediment basins need a calculated design volume; and, in this case, appropriate safety factors were incorporated in the analyses. Nonetheless, detailed analysis of a basin's specific watershed is recommended to refine the expected sediment volumes for final design.

Basin Name*	25-Year Sediment Storage Volume (ac-ft)	100-Year Sediment Storage Volume (ac-ft)	
Basin 1	0.8	1.2	
Basin 2	0.6	1.0	
Basin 3	0.7	0.8	
Basin 4	0.5	0.9	
Basin 5	0.2	0.3	
Basin 6	1.8	2.5	
*The basins listed in this table represent proposed mitigation structures that are part of the selected mitigation alternative			

#### Table 5-2. Sediment design volumes

# 5.4 RANCHOS DRAINAGE IMPROVEMENT ASSESSMENT

#### 5.4.1 Introduction

Initially, the ADMP scope of work included a driveway culvert assessment since the main drainage infrastructure throughout the Ranchos area are small roadside ditches designed to convey local (or onsite) runoff from the adjacent road and right-of-way from frequent recurrence interval storms (e.g., 2year, 5-year, 10-year, etc.). Residents generally access their property via a driveway that crosses a roadside ditch, and these driveways typically have small culverts that are designed to allow passage of runoff along the ditches (Figure 5-6).

However, after completing the existing conditions modeling, JEF determined that due to the infiltration methodology (SCS curve number) being applied in the study, the FLO-2D models were indicating minimal local runoff within the Ranchos area. That is, most of the localized on-site rainfall was absorbed through the selected curve numbers. Therefore, this task was modified to provide a concept drainage improvement assessment specific to the Ranchos area (Figure 5-7). This analysis included major roadway crossing improvements (excluding driveway culverts) within the Ranchos area that could potentially reduce offsite flood risk to the community even if the regional mitigation alternatives were not implemented.

Figure 5-6. Examples of typical driveway culverts in study area (note sediment clogging and available headwater depth).

Figure 5-7. Ranchos area vicinity map

#### 5.4.2 Methodology and Results

Prior to the development of the South Dayton area, runoff from the Pine Nut Mountain piedmont collected in a single drainage channel that flowed through what is now the Ranchos to the Carson River (see Section 1.4). Development of the Ranchos area encroached on the natural floodplain of the channel corridor. Although the historical alignment of the channel is mostly preserved, reaches of the present channel do not have capacity to convey the 100-year, 24-hour storm runoff without overtopping and flooding adjacent properties. In addition, the road crossing culverts do not have the capacity to pass either the 25-year or 100-year storm runoff without overtopping. As part of the ADMP, the consultant team prepared a concept that would improve drainage through the Ranchos community, exclusive of the regional mitigation structures in the selected alternative. The concept elements are described below and are shown spatially in Figure 5-8.

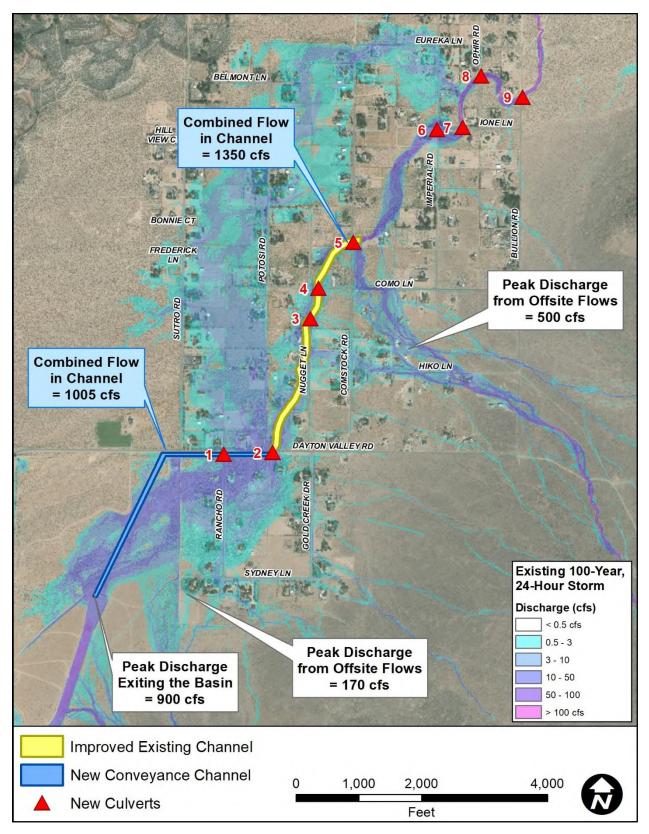

Figure 5-8. Drainage improvement concepts for the Ranchos area

#### 5.4.2.1 Basin Conveyance Channel

The existing 4,500-foot long basin that is located immediately east of the Dayton Valley Golf Course community releases stormwater upstream of the Ranchos. To better control this release, a new conveyance channel is recommended from the basin outlet to Dayton Valley Road. The conveyance channel would then need to extend east along Dayton Valley Road between Rancho Road and Gold Creek Drive, then through a new culvert beneath Dayton Valley Road. The ADMP FLO-2D modeling results indicate the outflow discharge from the basin is approximately 900 cfs for the 100-year, 24-hour storm and increases to 1,350 cfs within the Ranchos development due to additional inflows from both the south and east. However, the design flow rate for the new conveyance channel is 1,005 cfs since the major eastern inflows reach the channel downstream of the new channel (see Figure 5-8). Figure 5-9 shows a typical section for the new conveyance channel that would convey the 100-year discharge from the basin outlet to the new culvert at Dayton Valley Road. It should be noted that the basin outflow would increase if the outlet elevation was lowered. This analysis did not consider that possibility.

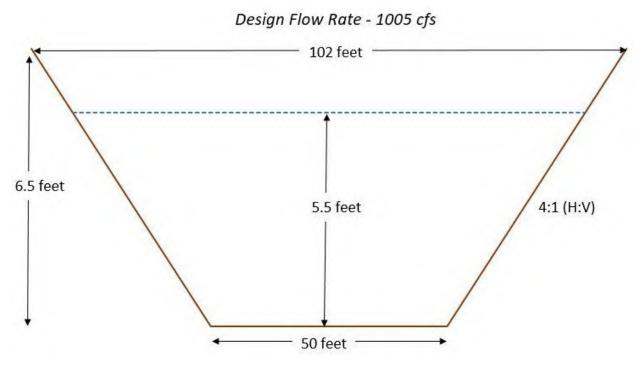

Figure 5-9. Typical section required for a new channel in the Ranchos

### 5.4.2.2 Existing Channel Improvements

The existing drainage channel within the Ranchos needs to be improved from Dayton Valley Road to downstream of Comstock Road to convey the runoff through the community for the 100-year storm. It is recommended that the existing channel be improved to the dimensions in the typical section shown in Figure 5-9. The ADMP modeling results and channel slope calculations indicate the existing channel from downstream of Comstock Road to Bullion Road generally has the capacity to convey the 100-year discharge; however, some sections show areas that would overtop by approximately 6 inches (see Figure 5-10). In addition, the culverts at major road crossings would need to be upgraded to pass the 100-year discharge without overtopping the road and causing adverse flooding to adjacent properties (Figure 5-11).

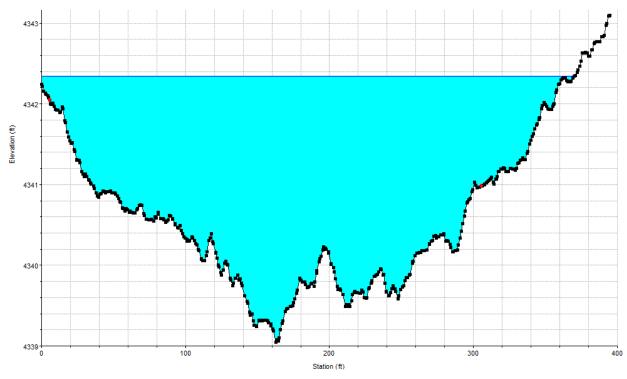

Figure 5-10. Example of cross-section with slight overtopping (see left bank)

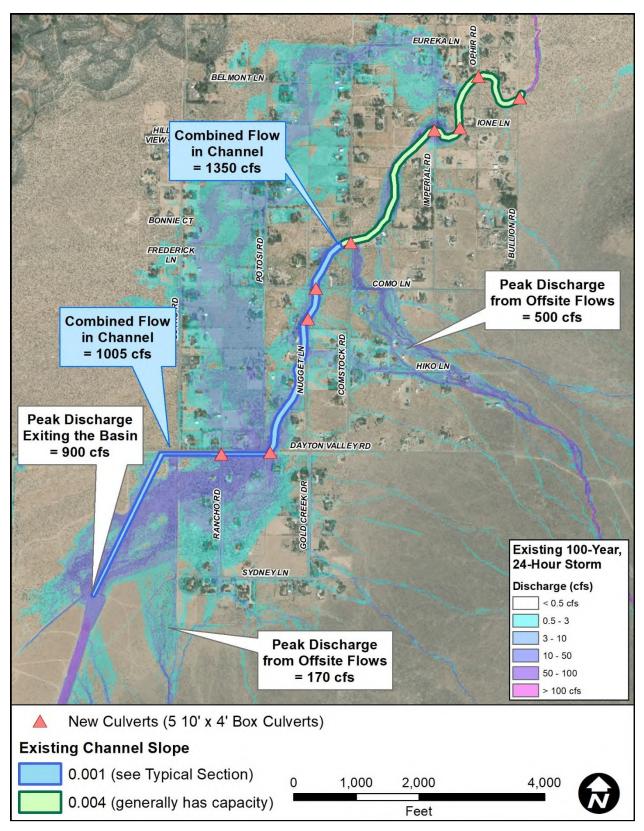

Figure 5-11. Approximate flow discharges and channel slope calculations

#### 5.4.2.3 Culverts

The new drainage system would necessitate construction of culverts at major road crossings that would allow for access to the development during a 100-year storm event. The recommended culvert locations are listed below in upstream to downstream order and shown spatially in Figure 5-8:

1. Ranchos Road

3. Nugget Lane

- 4. Como Lane
- 7. Ione Lane

- 2. Dayton Valley Road
- Comstock Road
   Imperial Road
- 8. Ophir Road
- Road
- 9. Bullion Road

The recommended culverts would allow passage of runoff without overtopping the roadway. A 5-barrel 10' x 4' box culvert at each road crossing would convey the 100-year discharge safely through the Ranchos community to the Carson River. This size of culvert crossing was chosen to keep the design headwater elevation less than 6 feet.

#### 5.4.2.4 Cost Estimates

Approximate cost estimates for each of the concept elements are listed in Table 5-3. These costs were developed based on the cost per lineal foot basis that Lumos developed for use on the regional alternatives (see Appendix B). Therefore, this estimate does not consider the cost of right-of-way (ROW) acquisition or drainage easements.

Mitigation Concept	100-Year Storm Cost Estimate
New Conveyance Channel & Existing Channel Improvements	\$6,100,000
New Culverts (9 total)	\$1,300,000
Total	\$7,400,000

### 5.5 SELECTED REGIONAL ALTERNATIVE CONCEPTUAL 15% DESIGN PLANS

Lumos was tasked with developing conceptual, 15% design plans for the mitigation alternative for the 25-year and 100-year storms. The Lumos plan sets and accompanying technical report are included in Appendix B. An example design plan excerpt is shown in Figure 5-12. These concept designs are meant to outline costs and general characteristics of the proposed structures to allow for recommendation and prioritization. The design volumes, structure alignments, and other characteristics should be refined during final design. There may be constraints such as utility conflicts uncovered during Final Design that are outside the scope of this study.

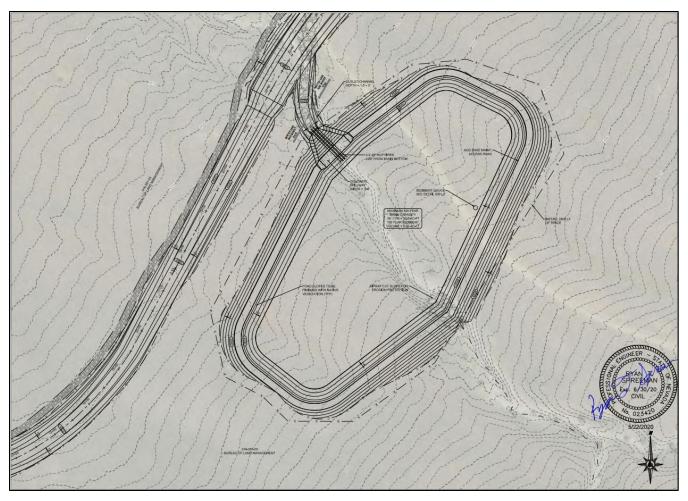

Figure 5-12. Example 15% design plan sheet for Basin #2

### 5.6 BENEFITS SUMMARY

### 5.6.1 Buildings Benefit

The depth and HAZUS analyses that were performed for existing conditions (Section 4) were repeated for the proposed conditions model results. The analyses were run using two scenarios for each of the three storm events for a total of six proposed conditions models. The scenarios were:

- 1) All 25-year proposed structures in place, and
- 2) All 100-year proposed structures in place

The proposed conditions building flood risk and HAZUS analyses are summarized in Table 5-4 and Table 5-5. The last column in the tables show the estimated benefit for each storm event when compared to existing base conditions for that same storm event.

	Propos	ed Conditions	s Building Cou	unts		
Recurrence Interval Storm	Building Count Flow Depth	Building Count Flow Depth	Building Count Flow Depth	Total Building Count	Existing Conditions Building Count <sup>1</sup>	Buildings Removed (Benefit)

1. May not be additive due to rounding in internal HAZUS calculations						

#### 5.6.2 Flood Risk Area Reduction Benefit

The selected alternative would result in a significant reduction in flood risk area throughout South Dayton. To quantify this benefit, the total flood risk area for depths of 0.25 feet and greater was computed from the existing conditions FLO-2D model results for both the 25-year and 100-year storms and subtracted from the inundation area resulting from the selected alternative models. The results are listed in Table 5-6 and shown in Figure 5-13 through Figure 5-16.

Recurrence	Flood Risk Inundation Area	Total Benefit			
Interval Storm	Acres	Acres Removed from Flood Risk (depth < 0.25 feet)			
	<b>Base Conditions</b>				
25Y24H	770	-			
100Y24H	1,165	-			
Propos	Proposed Conditions (25-year System)				
25Y24H	347	423			
100Y24H	751	414

25Y24H	337	433			
100Y24H	501	664			

Table 5-6. Potential	flood risk area	reduction benefit

#### 5.6.3 Flood Depth Reduction Benefit

The selected alternative would also result in a significant reduction in flood depths throughout the South Dayton area. To illustrate this benefit, Figure 5-17 through Figure 5-20 show the reduction in flood depth for the 25-year and 100-year storms considering both the 25-year and 100-year mitigation systems.

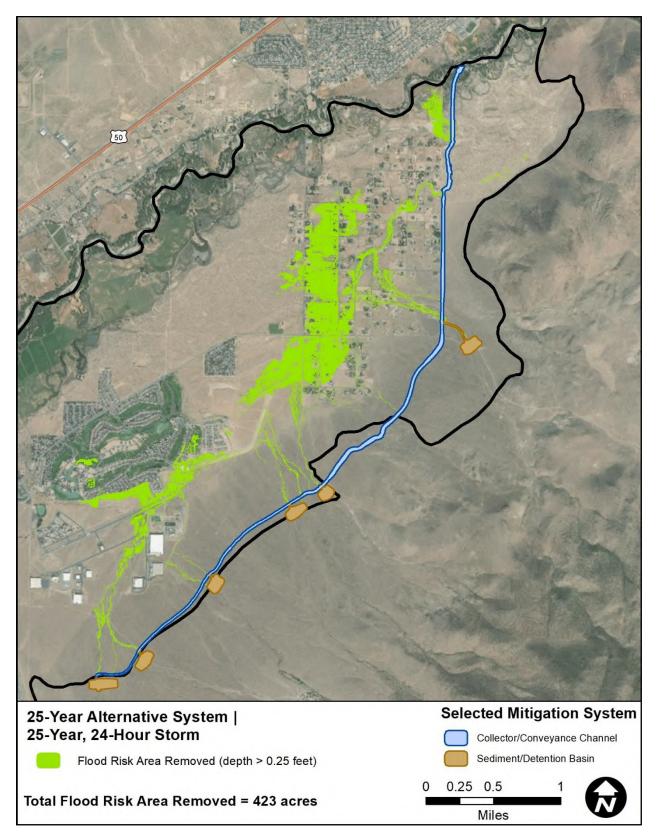

Figure 5-13. Potential flood risk area reduction benefit: 25-Yr Alt System, 25-Yr, 24-Hr storm

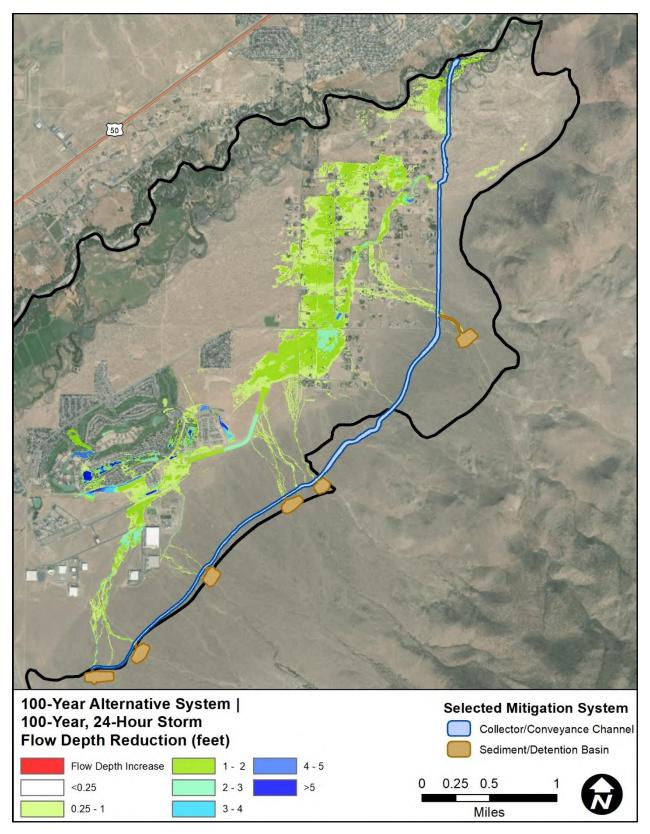

Figure 5-20. Potential flow depth reduction benefit: 100-Yr Alt System, 100-Yr, 24-Hr storm

### 5.7 FUTURE DESIGN CONSIDERATIONS

Preliminary FLO-2D modeling of the 15% design alternatives yielded items to be considered during final design:

- The dynamic nature of the upstream topography. Channels may shift, and new inlet locations may be needed.
- The overall sediment delivery to the Carson River should be analyzed in detail to ensure that the point source sediment delivery from the conveyance channel does not cause any adverse impacts.
- The sediment calculations used in this study were regional in nature and are generally applicable to channels with sandy bedload sediment. Some channels in the watershed were observed with coarser bedload sediment. A more site-specific sediment analysis is recommended for each structure during the final design process.
- If any mitigation system is implemented, the emergency spillways need to be carefully evaluated and designed to ensure that adverse impacts do not occur during larger events.

# **6 ADMP MITIGATION PRIORITIZATION**

The regional alternative structures presented in this report can be designed and constructed in phases as funding sources are identified and/or become available. Construction should occur beginning furthest downstream so as not to cause adverse flooding conditions due to point-source releases of stormwater. Other phasing strategies could be considered, but interim spillways and/or basins should be implemented to avoid adverse impacts until the full project is built.

Figure 6-1 shows a potential construction phasing strategy that could be implemented by Lyon County, while Table 6-1 lists a possible phasing schedule with associated costs. Note that the phasing cost for the conveyance channel was computed by dividing the total channel cost by the number of phases. The actual costs of each phase of channel construction may vary from those in Table 6-1 due to variability in channel geometry and erosion protection and that if phased into multiple construction contracts, certain bid items such as mobilization will be increased

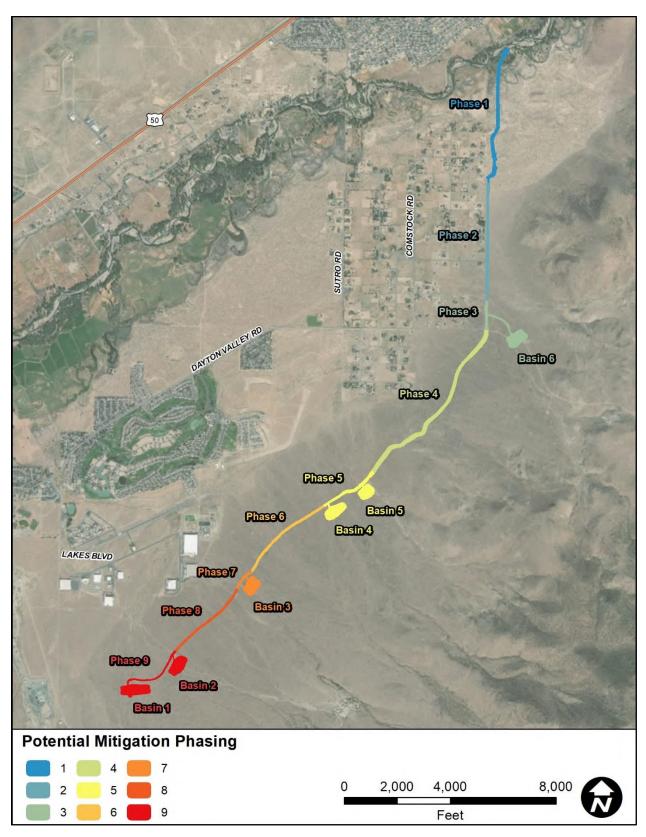

Figure 6-1. Potential mitigation construction phasing

Phase	Structure Elements	25-Year Structure Cost Estimate <sup>2</sup>	100-Year Structure Cost Estimate <sup>2</sup>	
Phase 1	Conveyance Channel (5,200 LF <sup>1</sup> )	\$3,030,000	\$4,500,000	
Phase 2	Conveyance Channel (4,500 LF)	\$2,600,000	\$3,800,000	
Phase 3	Conveyance Channel (1,100 LF) Basin #6	\$700,000 \$2,400,000	\$970,000 \$2,800,000	
Phase 4	Conveyance Channel (7,200 LF)	\$4,200,000	\$6,100,000	
Phase 5	Conveyance Channel (2,300 LF) Basin #5 Basin #4	\$1,350,000 \$1,100,000 \$3,100,000	\$2,000,000 \$2,200,000 \$4,400,000	
Phase 6	Conveyance Channel (3,700 LF)	\$2,200,000	\$3,200,000	
Phase 7 Conveyance Channel (900 LF) Basin #3		\$515,000 \$2,000,000	\$760,000 \$3,200,000	
Phase 8	Conveyance Channel (3,300 LF)	\$1,950,000	\$3,000,000	
Conveyance Chanel (2,500 LF) Phase 9 Basin #2 Basin #1		\$1,500,000 \$2,000,000 \$2,600,000	\$2,200,000 \$2,200,000 \$3,000,000	
<ol> <li>LF = linear feet (approximate)</li> <li>Construction costs have been rounded for simplification. See Appendix B for a detailed breakdown of cost estimates.</li> </ol>				

Table 6-1. Potential mitigation construction phasing cost

### 6.1 POTENTIAL FUNDING SOURCES

There are numerous potential grant sources that could be explored by the South Dayton community and Lyon County to partially or fully fund the alternatives presented in this study. Some examples of grants that can be obtained are shown in Table 6-2.

#### Table 6-2. Potential grant funding sources

Grant	Funding Agency	Qualifications	Description
Building Resilient Infrastructure and Communities (BRIC) [formerly Pre- Disaster Mitigation (PDM)]	FEMA	FEMA approved Hazard Mitigation Plan <sup>1</sup> .	Funds the planning, design and construction of mitigation projects and provides opportunities for raising public awareness about reducing future losses before disaster strikes. BRIC grants are awarded to projects that show a net benefit, i.e. a benefit cost ration greater than 1.
Flood Mitigation Assistance (FMA)	FEMA	Must protect National Flood Insurance Program (NFIP) insured properties/structures. Requires a FEMA approved Hazard Mitigation Plan that must include Flood as one of the hazards <sup>1</sup> .	Funds awarded to projects and planning efforts that reduce or eliminate long-term risk of flood damage to structures insured under the NFIP. Includes the Repetitive Loss Program.
Hazard Mitigation Grant Program (HMGP)	FEMA	Requires a Presidential Major Disaster Declaration. 25% cost share from applicant. FEMA approved Hazard Mitigation Plan <sup>1</sup> .	Funding for projects listed in the community's Hazard Mitigation Plan. Funds are only released if there is a Federally declared disaster.

Grant	Funding Agency	Qualifications	Description
Planning Assistance to States (PAS)	USACE	None Application for PAS is typically started through consultation with the regional USACE District office. Planning only – no construction. (Difficult to obtain and usually over- prescribed)	Upon request and funding availability, USACE will cooperate with non- federal public sponsors in the preparation of plans for the development, utilization and conservation of water and related land resources located within the boundaries of the state. Assistance is given within the limits of available appropriations, but \$2,000,000 is the maximum federal funding available annually to any state or tribe. A 50-percent cost share is required by the non-federal sponsor.
Continuing Authorities Program (CAP) Section 205 — Small Flood Risk Management Projects. Authorized by Section 205 of the Flood Control Act of 1948, as amended.	USACE	None Application for PAS is typically started through consultation with the USACE District office. (Difficult to obtain and usually over- prescribed)	Work under this authority provides for local protection from flooding by the construction or improvement of flood control works such as levees, channels, and dams. Non- structural alternatives are considered and may include measures such as installation of flood warning systems, raising and/or flood proofing of structures, and relocation of flood prone facilities. The feasibility study phase is federally funded up to \$100,000. Study costs in excess of \$100,000 are shared 50 percent Federal and 50 percent by the project sponsor. The project sponsor will be required to sign a feasibility cost-sharing agreement when study costs exceed \$100,000.

6.2 ADMP LIMITATIONS

While the results are based on detailed topography, hydrology, and hydraulic modeling, they represent the existing conditions as of the date of the LiDAR mapping. Because of the unique landform and sediment characteristics of the watershed, the topography and distribution of flow can be very dynamic (i.e., small culverts or drainage channels can quickly fill with sediment causing water to change course from what it was previously). Therefore, during final design of any of the alternatives, or prior to any future development within the project area, a detailed assessment of upstream flow distribution should be undertaken.

Furthermore, this study did not analyze rain on snow events, flooding recurrence intervals greater than 100-year, or post-wildfire flooding events. These types of events are considered outside the scope of the typical area drainage master plan process. The hydrology used in this study was state of the art, engineering design storms based on recent NDOT research. These atypical events could create hydraulic conditions that exceed these design storms.

### **1** Introduction and Specifications

Digital Aerial Solutions, LLC (DAS) was tasked to collect and process a Light Detection And Ranging (LiDAR) derived elevation dataset for the G17PD01257, NV Reno Carson City Urban LiDAR. The area encompasses approximately 1534 square miles Aerial LiDAR data was collected utilizing a Leica ALS80. The ALS80 is a discrete return topographic LiDAR mapping system manufactured by Leica Geosystems. LiDAR data collected for the G17PD01257, NV Reno Carson City Urban LiDAR survey has an Aggregate Nominal Pulse (ANPS) spacing of (QL1 0.35 meters) and (QL2 0.7 meters), and includes up to 4 discrete returns per pulse, along with intensity values for each return.

LiDAR datasets were post processed to generate elevation point cloud swaths for each flight line. Deliverables include the point cloud swaths, tiled point clouds classified by land cover type, breaklines to support hydro-flattening of digital elevation models (DEM)s, intensity tiles, and bareearth DEM tiles. The point cloud deliverables are stored in the LAS version 1.4, point data record format 6. The tiling scheme for tiled deliverables is a 1000 meter x 1000 meter grid. Tile number is the appropriate cell number values found in the USNG index. All deliverables were generated in conformance with the U.S. Geological Survey National Geospatial Program Guidelines and Base Specifications, Version 1.3.

### 2 Spatial Reference System

The spatial reference of the data is as follows:

#### **Horizontal Spatial Reference**

- Coordinates: UTM Zone 11 N, Meters (to 2 decimal places)
- Datum: North American Datum 1983 (2011), Meters (to 2 decimal places)

#### **Vertical Spatial Reference**

All datasets are available with orthometric elevation; point cloud datasets are also available with ellipsoid heights.

- Datum: North American Vertical Datum of 1988 (GEOID12B)

## **3 LiDAR Acquisition**

#### 3.1 Survey Area

The NV Reno Carson City Urban LiDAR survey covers approximately 676 square miles for the QL1 area of interest and 858 square miles for the QL2 area of interest. Totaling 1534 square miles covering all of Washoe, Storey, Carson City and Lyon counties in NV. The flight plan consisted of 610 survey lines and 4 control lines.

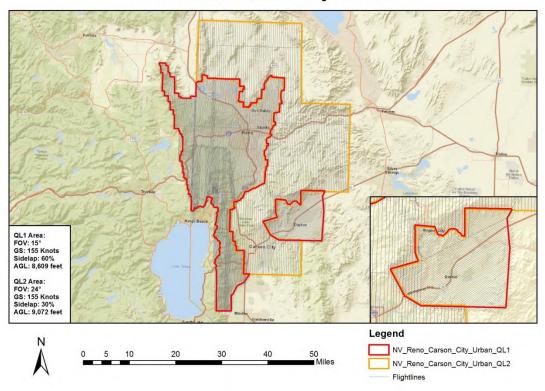

Image 2: NV Reno Carson City Urban LiDAR Flightlines

### **3.2 Acquisition Parameters**

Acquisition parameters include the sensor configuration and the flight plan characteristics, and are selected based on a number of project specific criteria. Criteria reviewed include the required accuracies for the final dataset, the land cover types within the project survey area, and the required

nominal pulse spacing. Aggregate Nominal Pulse Density (ANPD) for QL1 AOIs are no less than 8ppsm and for the QL2 AOIs are no less than 2ppsm. The project parameters are summarized below.

Parameter	QL1	QL2
Flying Height Above Ground Level:	8,609 feet	9,072 feet
Nominal Sidelap:	60%	30%
Nominal Speed Over Ground:	155 Knots	155 Knots
Field of View:	15°	24°
Laser Rate:	220.2 kHz	206.2 kHz

### **3.3 Acquisition Mission**

The acquisition mission for the G17PD01257, NV Reno Carson City Urban LiDAR survey was coordinated for optimal collection conditions and was acquired within 6 weeks. Collection began on September 19, 2017 and was completed on October 27, 2017.

### 3.4 Airborne GPS/IMU

Airborne global positioning system (GPS) and inertial measurement unit (IMU) data was collected on the aircraft during the acquisition mission, providing sensor position and orientation information for geo- referencing the LiDAR data. Airborne GPS observations were collected at a frequency of 2Hz, and IMU observations are collected at a frequency of 200Hz.

Aircraft	Sensor	GPS Lever Arm (m)	IMU Lever Arm (m)		
C421-N12RF	ALS80 SN# 8137	X: -0.153, Y: -0.055, Z: -1.361	X: -0.219, Y: 0.297, Z: 1.192		
Table 2: Aircraft and Lover Arms					

Table 2: Aircraft and Lever Arms

GPS data was collected with ground base stations during the acquisition missions, providing corrections to support differential post-processing of the airborne GPS. Base stations were setup at

Minden-Tahoe Airport NV. Ground GPS observations were collected at a frequency of 2Hz. The use of three CORS stations was also employed to support data acquisition for the project area. The following table's list the positions used in to post-process the airborne GPS.

Name	Latitude	Longitude	Ellipsoid (m)
Minden-Tahoe Airport – KMEV	38° 59' 52.40797"	-119° 45' 22.01331"	1409.811

Table 3: Base Stations locations

### **4 LiDAR Processing**

### 4.1 Acquisition Post-Processing

For each mission, airborne GPS was differentially corrected using the ground base station GPS for the corresponding day in Leica's IPAS software. The resulting solution is check to assure an accuracy of +/- 3 cm combined separation for north, east and height position difference between the forward and reverse processing solutions.

Differentially corrected airborne GPS data was merged with the airborne IMU dataset in Leica's IPAS software through Kalman filtering techniques. IPAS applies the reference lever arms for the GPS and IMU measurement systems during processing to determine the trajectory (position and orientation) of the LiDAR sensor during the acquisition mission. Estimated lever arm values reported posteriori validate the measurements made during sensor installation in the aircraft.

Raw LiDAR sensor ranging data and the final sensor trajectory from IPAS were processed in Leica's ALSPP software to produce the LiDAR elevation point cloud swaths for each flight line, stored in LAS version 1.2 file format. Quality control of the swath point clouds was performed to validate proper function of the sensor systems, full coverage of the project AOI, and point density consistent with the planned nominal pulse spacing.

Swath point clouds were assigned a unique File Source ID within the LAS file format before further processing. Swath files for the G17PD01257, NV Reno Carson City Urban LiDAR project were numbered in chronological order of acquisition.

### 4.2 Geometric Calibration

Geometric and positional accuracy of the LiDAR swath point clouds is highly dependent on accurate calibration of the various subsystems within the LiDAR sensor system. Sensor calibration parameters fall into two categories, one being those parameters proprietary to the manufacturer's sensor design, and the other being parameters common to most commercial airborne LiDAR sensors, the IMU to laser reference system alignment angles (bore-site), and mirror deformation constants (scaling).

The manufacturer specific calibration parameters are applied in Leica's ALSPP software for the Leica ALS80 sensor system. Terrasolid's Terramatch software was used to calculate the IMU bore-site and mirror scale parameters for the G17PD01257, NV Reno Carson City Urban LiDAR. Within the TerraMatch software, the Tie- line workflow was used to solve for the parameters. The Tie-line workflow involves automated selection of numerous 'tie-lines', which represent a linear segment fit to the data that should have the same slope, azimuth, position and elevation, within the overlap sections of the survey lines and control lines. The tie- lines provide observations for algorithms within TerraMatch to solve for the bore-site and mirror scale parameters for the lift.

The Tie-line workflow is dependent upon well distributed tie-lines throughout the swath point clouds to effectively solve for bore-site and mirror scale parameters with the automated algorithms.

Manual estimation of the bore-site and mirror scale parameters was performed using the observed tie-lines in overlap areas.

The final step of geometric calibration is to determine elevation (z) offset corrections to be applied to the swath point clouds. The Z values calculated during the course of the acquisition mission can vary at the centimeter level as the GPS satellite constellation observed in the survey area changes with satellites moving through their orbits over the course of the mission. Baseline length from the ground base station GPS to the airborne GPS can also impact the z values calculated for the swath point clouds. The Z offset corrections are calculated in two steps; a relative step, where individual lines are corrected one to another using the adjusted tie-lines from the bore-site and mirror scale calculation step; and an absolute step, where groups of lines are leveled to project ground control.

For G17PD01257, NV Reno Carson City Urban LiDAR project, the control lines were used to determine relative z offset corrections in areas of discernible ground. The ground control points listed below were used to adjust the LiDAR by an average of -0.180 cm.

Point Id	Easting	Northing	Orth. Height

Table 5: Ground Control Points

The final geometrically calibrated swath point clouds were compared to the bare-earth profile survey data. The data fit the profile surveys within the vertical accuracy tolerance specified for the project. Full documentation of the vertical accuracy checks maybe found in section 5.1.

### 4.3 Point Cloud Classification

Georeference information was applied to the swath point cloud LAS files. Geometrically calibrated swath point clouds were cut into USNG index, 1000 meter x 1000 meter LAS 1.2 format tiles for point cloud classification and derived in LAS 1.4 format for product creation.

Tiled point cloud data was processed in Terrasolid's Terrascan software to assign initial classification values. The Terrascan software provides a number of routines to algorithmically detect and assign points to their appropriate class. Points left unclassified by the algorithmic routine remain as Class 1

- Processed, but unclassified. Automated classification routines assigned points to one of the following classes:

```
Class 1 - Processed, but unclassified
Class 2 - Bare-earth ground
Class 7 - Low Noise (low, manually identified, if necessary)
Class 9 - Water
Class 17 - Bridge Decks
Class 18 - High Noise (high, manually identified, if necessary)
Class 20 - Ignored Ground (Breakline Proximity)
```

Automated classification results were reviewed for each tiled point cloud, and manual edits made where necessary to correct for misclassified points. Points remaining in Class 1 after the automated classification routines were run were left in Class 1. Points falling outside of a 100 meter buffer of the project AOI polygon were excluded from the tiled point clouds.

### 4.4 Breakline Collection

Manual breakline collection was performed to support the hydro-flattening requirements of the project's DEM deliverables. Breaklines were collected directly from the classified point clouds and from triangulated irregular network (TIN) surface models built from the classified point clouds, in Terrasolid's Terrascan and Terramodeler software. Breakline features were collected as design file elements in Bentley's Microstation software. Breaklines were converted to ESRI 3D shapefile format for the breakline deliverable, and tiled to USNG index.

The data collected for the G17PD01257, NV Reno Carson City Urban LiDAR survey maintained significant point density in the water, marsh, and swamp, limiting the usefulness of point density as guiding factor in breakline placement.

Points classified as Class 2 – Bare-earth ground, falling within a one meter buffer of the collected breaklines, were reassigned to Class 20 – Ignored Ground. These points are excluded from the surface model during DEM generation to preserve the hydro-flattening characteristics of the breaklines.

#### **4.5 DEM Generation**

The final classified point clouds and collected breaklines were reviewed for completeness and conformance to the task order scope of work. Within the Terramodeler software, points in Class 2 – Bare- earth ground and the breaklines were combined to generate TIN elevation models for each tile, from which the bare-earth DEM tiles were interpolated and exported as ERDAS Imagine 32-bit floating point raster format ".img" format.

### **5 Quality Control**

### **5.1 Point Clouds**

Accuracy and completeness of the LiDAR point clouds directly impacts the quality of all other derived LiDAR derived products. Ensuring a quality LiDAR dataset begins with proper mission planning and execution. Ground GPS base stations are located such that GPS baselines between the ground and airborne receivers do not exceed 30km. For the G17PD01257, NV Reno Carson City Urban LiDAR project, two base stations were run to meet this requirement, one at the field operations airport and one within the survey area. Static alignment is performed both before take-off and after landing to allow for GPS integer ambiguity resolution. Sensor operators carefully monitor the LiDAR unit and its various subsystems during the acquisition mission to ensure proper function. Airborne GPS positional dilution of precision (PDOP) estimates are monitored to ensure they remain less than 3.The optical system is monitored to ensure there are no ranging errors encountered during the flight lines.

During acquisition post-processing estimates of the trajectory data accuracy are reviewed to ensure they will support the required accuracies of the point cloud data. The trajectory accuracy is a function of the differentially corrected GPS data and the IMU data. The raw swath point clouds generated from ALSPP are reviewed as another check for proper sensor function. The point clouds are reviewed for full coverage of the AOI, required point density and nominal pulse spacing, clustering, proper intensity values, full swath coverage within the planned field of view, and planned survey line overlap.

Geometric calibration quality control validates that the positional accuracy requirements of the project are met, and includes relative accuracy assessments for intra-swath (within) and inter-swath (between) accuracy, along with absolute accuracy assessments against project ground control.

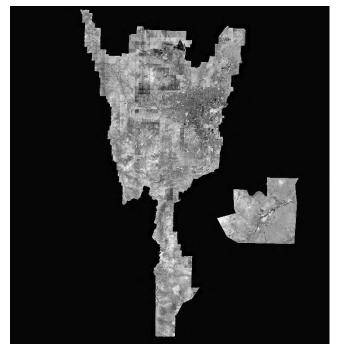

Image 3: NV Reno Carson City Urban LiDAR QL1 Intensity Image

Relative vertical accuracy assessments are normally made using the tie-lines generated in the Terramatch software, as these lines provide positional observations throughout the extent of individual swaths, and between neighboring swaths.

This data set was produced to meet ASPRS "Positional Accuracy Standards for Digital Geospatial Data" (2014) for a 22.6 (cm) RMSEx / RMSEy Horizontal Accuracy Class which equates to Positional Horizontal Accuracy =+/- 78.3 cm at a 95% confidence level.

Estimated LiDAR Horizontal:	(cm)
Error Per Point (RMSE <sub>R</sub> )	32.0
Error Per Point (RMSE <sub>x</sub> /RMSE <sub>y</sub> )	22.6
Per Point at 95% confidence level	78.3

Table 6: Estimated LiDAR Horizontal Accuracy

Absolute vertical accuracy assessments for the point cloud data are made against ground check point data. For the G17PD01257, NV Reno Carson City Urban LiDAR, ground check point data consisted of the ground GPS base station and real-time kinematic (RTK) GPS techniques.

Check point locations were collected at 1 – second intervals during the RTK survey. Points collected during the static pre-initialization and post-initialization was removed from the assessment so as not to bias the assessment.

Local TIN models of the elevation points are built around each ground check points. The tin model elevation is sampled at the horizontal position of the ground check point. The TIN model elevation and ground check point survey elevation values were used to calculate the Non-vegetated Vertical Accuracy (NVA) of the swath point clouds. The NVA of the TIN tested RMSEz 0.051 meters and 0.100 meters at the 95% confidence level in open terrain. NVA of the DEM tested at an RMSEz of 0.053 meters and 0.104 meters at the 95% confidence level in open terrain. The full calculations for all check points can be found in Appendix B.

N۷	A of TIM	J
RMSE <sub>z</sub> =	0.051	meters
NSSDA =	0.100	meters

Table 7: Tested NVA of tin from Classified Point Cloud.

NV	A of DEI	N
RMSE <sub>z</sub> =	0.053	meters
NSSDA =	0.104	meters

Table 7: Tested NVA of Digital Elevation Model.

The tiled point cloud products were reviewed for full coverage of the AOI and proper classification. As part of the QC process, TINs are built in the Terramodeler software for each tile using the ground class and the hydro-flattening breaklines. The TINs are reviewed for non-ground features, and edited where necessary to remove any remaining non-ground features. Points were also reviewed for absolute elevation, and points falling below the selected orthometric elevation for water were removed from the ground class.

#### **5.2 Breaklines**

The final breaklines in ESRI 3D shapefile format were reviewed for topological consistency and correct elevation. Breaklines features are continuous and do not have overlaps or dangles.

#### **5.3 Digital Elevation Models**

Digital elevation models (DEMs) were reviewed for conformance with the SOW and the Base Mapping Specification version 1.3 guidelines. DEM files were loaded in the Global Mapper software and inspected visually for edge matching between tiles, void areas within the project AOI, and proper coding of the NODATA values. DEM file naming was verified for consistency with the USNG index.

**Appendix B. Vertical Accuracy Calculations** 

### **Project Information**

Prepared By: Kenneth L Coffey Project Name: NV Reno Carson City Sensor Info: Leica ALS80 Required Nominal Pulse Spacing: 0.35 Vendor Name: Digital Aerial Solutions .LLC Units: Meters Percent of Extent Tolerance: Extents Not Checked Date of Aquisition: Start: 9/19/2017 Finish: 10/27/2017

#### Metadata Information

Tile Index: Filename: CLIP\_NV\_1K\_LAS\_Tiles.shp Number of Polys: 0 Intensity: Tile Index Attribute: Not Specified Data Filename: Not Specified

DEM:

Tile Index Attribute: NAME Data Filename: Clipped

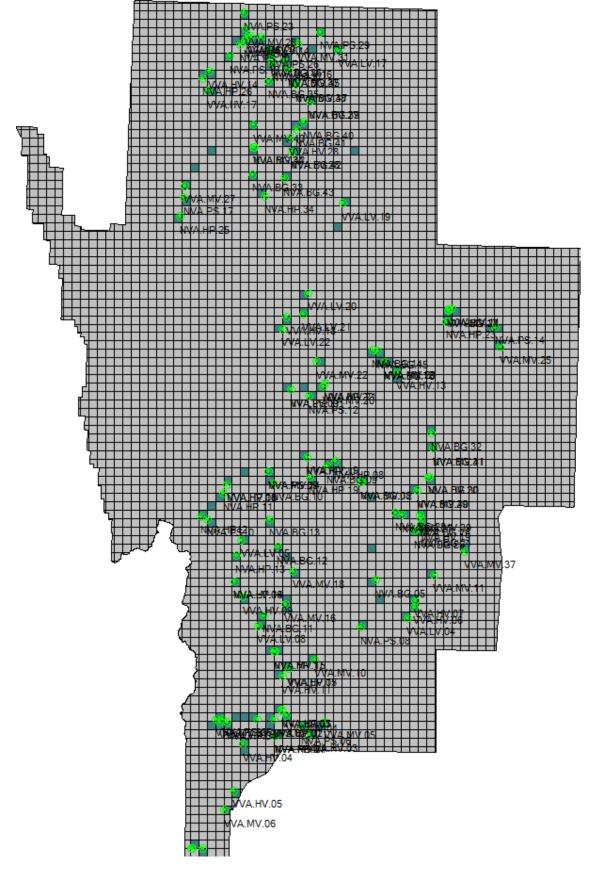

#### LAS:

Tile Index Attribute: NAME Data Filename: LAS

## Tiled-Data Area

# Introduction

Lumos & Associates has completed the preliminary modeling and design of the selected mitigation alternative for the Dayton Valley Area Drainage Master Plan (ADMP) being prepared for Lyon County. Conceptual designs developed as part of this project will be used for the collection and conveyance of stormwater that impacts the Dayton Valley on the south side of the Carson River. Data used for the preliminary modeling and design sizing was provided by JE Fuller as part of their analysis of upstream tributaries and watersheds that affect the project area. This report presents a summary of the assumptions and process for the development of the 15% conceptual design plans, as well as the estimated construction and maintenance costs for all alternatives.

## Conceptual Design

Three primary alternatives were created by JE Fuller to mitigate stormwater runoff impacts and flooding within the southern portion of the Dayton Valley. The selected mitigation alternative includes a diversion channel and six sedimentation basins. The other mitigation alternatives considered include smaller systems, directing tributary runoff to existing retention features and diversion structures. The estimated costs for such alternatives are based on per-unit prices of the selected alternative and are provided in subsequent sections of this report. The locations of the three mitigation alternatives considered are shown on Figure 1 in Attachment A.

The diversion channel, proposed as part of the selected mitigation alternative, extends from approximately two-thirds of a mile south of West Airpark Vista Boulevard and terminates at the Carson River north of Bullion Road. The total length of the diversion channel is approximately eight miles and includes six different reaches. Each reach increases in size as the channel intercepts flows from additional tributaries. The diversion channel location was designed to parallel the location of the planned regional bypass road provided by Lyon County. The roadway is planned to extend from Dayton Valley Road, routing traffic away from downtown Dayton, to the intersection of Highway 50 and Chaves Road. All efforts were made to take the future location of the bypass road into consideration while designing the channel on the downhill gradient. Due to the required gradient of the channel, the roadway should be designed to remain downstream of the channel to limit the size and number of culverts that would be required to pass tributary runoff below the roadway. The channel should be used to control the impacts of offsite runoff for the roadway. The six sedimentation basins for the selected mitigation alternative are placed above the diversion channel in tributaries where runoff is more concentrated. The proposed basins are intended to limit sediment transport by attenuating channel velocity through detention. Detaining storm water allows time for sediment to separate from the water and settle to the bottom of the basins. The six basins are sized with additional capacity to accommodate the accumulation of sediment.

The conceptual design plans produced for the selected mitigation alternative includes design options sized for the 25-year and 100-year storm recurrence intervals. The two design scenarios were analyzed to provide perspective for different levels of storm protection and the associated range of

costs. Conceptual diversion channel designs for the 100-year option are sized to fully convey the 100year, 24-hour storm to the Carson River with approximately one foot of freeboard. Super elevation of the water surface in critical sections and at channel bends was not considered for the preliminary designs, but the low Froude number suggests that super elevation will not be significant. Conceptual detention basins designed for the 100-year option are sized so that the water level within each detention basin is at the bottom of the spillway, i.e. freeboard elevation, during the design storm event. Similarly, diversion channels designed for the 25-year option are sized to safely convey the 25-year, 24-hour storm to the river. Conceptual detention basins for this storm event are sized so the water level in each detention basin is at freeboard elevation during the design storm. Conceptual designs for the 25-year option provide a reduction in cost while still offering a minimal level of protection for the impacted area. Itemized costs for each design storm option are provided in Attachment B and will be discussed in subsequent sections of this report.

The proposed detention basins for all mitigation alternatives were analyzed using the U.S. Army Corps of Engineers (USACE) Hydrologic Engineering Center's Hydrologic Modeling System (HEC-HMS), version 4.3. Modeling was performed for the 25- and 100-year storm events. Inflow hydrographs were obtained from JE Fuller's modeling effort, and input directly into the HEC-HMS application as discharge gage time-series data. Basin volumes and outlet structure configurations were then assigned based on site constraints and the Nevada Division of Water Resources (NDWR) dam permit regulations. NDWR requires plan review for any water impoundment greater than 20 acre-feet, and an annual fee and inspection process for impoundments greater than 50 acre-feet. Due to these regulations, all basins were optimized to store less than 50 acre feet, and some basin designs were kept below the 20 acre-foot threshold. Additionally, basin size was restricted by existing property boundaries, terrain features, and topography. The shape of each basin was designed to conform to the existing terrain in order to minimize the amount of earthwork and excavation necessary. Outlets were sized to reduce the existing runoff flow rates to the greatest extent possible given basin size constraints. All basins were designed so that flood waters will be directed over armored spillways. Outlet invert elevations were sized to store the sediment volume transported by the design storm event, as modeled by JE Fuller. To ensure that the basins remain functional, it is recommended that detention basins are maintained and sediment is removed as outlined in this report. Detention basin characteristics for the 25- and 100-year configurations are shown in Table 1:

		25-yea	ir		100-year					
System	Storage	Sediment	Total	Outlet	Storage	Sediment	Total	Outlet		
Name	(ac-ft)	Storage (ac-ft)	Depth (ft)	Pipes	(ac-ft)	Storage (ac-ft)	Depth (ft)	Pipes		
Basin 1	33.4	0.79	8.0	3 x 30″	45.6	1.19	8.5	4 x 42"		
Basin 2	25.3	0.58	7.5	2 x 36"	30.6	0.95	8.0	3 x 48″

Basin 4	23.2	0.50	7.5	2 x 36"	31.1	0.90	8.0	3 x 48″		
Basin 5	12.3	0.24	6.5	1 x 24″	20.7	0.31	7.5	2 x 24"		
Basin 6	21.6	1.84	7.5	2 x 36″	37.2	2.49	8.0	3 x 42"		

Table 1: Detention Basin Design Characteristics

Diversion channel reaches for the 25- and 100-year selected mitigation alternative were sized using Bentley FlowMaster® V8i with output data from HEC-HMS, version 4.3. Channels were modeled as reaches within the detention basin 24-hr simulation using junctions at each basin outflow location. Channels were modeled in such a manner that time of concentration was critical in minimizing channel discharge. Diversion channel reaches are trapezoidal with side slopes of 5H:1V to limit channel velocities, reduce the tractive stress for riprap placement, and limit the need for robust erosion protection measures. Channel transitions between reaches were sized to minimize surface disturbances and were estimated to be approximately 35' in length using equation (847) in the Truckee Meadows Regional Drainage Manual TMRDM. Channel dimensions were selected to maintain a Froude number during design storms of less than 0.85 for subcritical reaches and greater than 1.2 for super critical reaches. Channel reaches with design velocities less than five feet per second will be vegetated, and channel reaches with a design velocity greater than five feet per second will be riprap lined. Preliminary riprap sizes were determined using Tractive Stress Method. Channel designs and dimensions conform to the requirements outlined in the Truckee Meadows Regional Drainage Manual, and to the 2018 Lyon County Drainage Guidelines. Design characteristics for each reach of the selected mitigation alternative diversion channel are shown in Table 2:

_	25-year					100-year					
Channel	Flow	Bottom	Total	Max.	Max.	Flow	Bottom	Total	Max.	Max.	
Reach	Rate	Width	Depth	Velocity	Slope	Rate	Width	Depth	Velocity	Slope	
	(cfs)	(ft)	(ft)	(fps)	(%)	(cfs)	(ft)	(ft)	(fps)	(%)	
Reach 1	165	10	3.0	3.6	0.32	420	25	3.5	4.3	0.44

 Table 2: Diversion Channel Design Characteristics

A net excavation of 723,000 cubic yards of earth would be required for the conceptual 25-year basin design, and a net excavation of 954,000 cubic yards would be required for the 100-year conceptual basin. Cost estimates were based on the assumption that this material would be hauled to offsite facilities or buyers near the Dayton area. The earthwork volumes required to construct each detention basin and diversion channel option are provided in Table 3:

Feature Name	25-year	Option	100-year Option			
reature Name	Cut (Cu Yd)	Fill (Cu Yd)	Cut (Cu Yd)	Fill (Cu Yd)		
Basin 1	108,600	6,450	125,400	9,400		
Basin 2	86,800	10,550	93,500	12,500		
Basin 3	77,000	3,100	136,800	7,100		
Basin 4	135,100	3,600	190,750	5,000		
Basin 5	46,250	3,900	94,300	4,850		
Basin 6 and Conv. Channel	71,600	12,600	85,700	26,300		
Diversion Channel	321,800	84,000 439,000		146,600		
Net Cut	723	,000	954,000			

Other cost items considered for the conceptual designs of the diversion channel and detention basins include erosion protection, concrete, outlet pipes, and fencing. Vehicle access and turnaround was not considered in the preliminary design, but an assumed cost for basin access was added to the cost estimates. Riprap sizes were conceptually designed for turbulent areas of the diversion channel and where channel design flow rates exceed five feet per second. Design details for each facility can be found in the 15% conceptual plan set.

## Preliminary Cost Estimates

Preliminary construction cost estimates were prepared for the selected mitigation alternative. The preliminary cost estimate includes itemized quantities and costs for the 25-year and 100-year design options. The 100-year designs require larger and deeper basins and channels, larger erosion protection measures, and larger spillway infrastructure resulting in a higher cost than the 25-year designs. Unit prices for the estimate were gathered from compiled average awarded bid data from state department of transportation construction bids across the United States. Non-construction costs were also considered, which include additional environmental and agency permitting, design, and construction services. Permitting is expected to include NDWR damn permitting, BLM permitting since majority of the proposed improvements reside on public land, and county building permits. The total estimated cost for the 25-year storage alternative is approximately \$28,200,000 compared to the 100-year storage alternative at a cost of roughly \$44,000,000.

The selected mitigation alternative has been designed to function as a system; however, if funding cannot be provided for the entire project, the project can be phased starting with the downstream improvements. For example, Reach 5, Reach 6, and Basin 6 should be constructed prior to upstream channel reaches and basins. Whether the 25- or 100-year design is selected, the entire system would have to be constructed to discharge to the Carson River. Basins should be constructed sequentially from Basin 6 to Basin 1. If basins are not constructed in that order, uncontrolled runoff entering the system could overwhelm the diversion channel, and breakouts could occur flooding areas not typically flooded.

Preliminary cost estimates were also determined for the non-selected mitigation alternatives. These alternatives were not selected to be designed based on land ownership or topography constraints, but estimated costs are provided for comparison. Since Alternatives 1A and 1B were not designed, estimated costs are developed using a multivariable regression with data from the selected mitigation alternatives and from the Area Drainage Master Plan developed for the north side of the Dayton valley. This data was input into the multivariable regression as dependent variables. These dependent variables include channel length, channel flow rate, basin peak inflow, and basin capacity. Other design factors were determined to not have a significant impact on total cost, as determined using the "p-value" for the regression, and were not included in the analysis. The equations developed using the multivariable regression are provided in equations (1) and (2):

$$Y[channel] = 697.37(LF) + 514.77(Q) \tag{1}$$

And,

$$Y[basin] = 107,450.10(CF) - 1,444.51(Q)$$
(2)

Where,

Y = Estimated alternative cost in dollars;

LF = Channel length in linear feet;

Q=Channel flowrate or basin inflow in cfs;

CF=Basin volume in cubic feet.

Non-selected mitigation Alternative 1B requires the installation or replacement of approximately 10 culverts. Culvert costs were determined using data from compiled average awarded bid data from state department of transportation construction bids. A summary of costs for the non-selected mitigation alternatives are provided in Table 3 below:

Table 3: Non-selected Mitigation Alternative Estimated Costs

Estimated costs for non-selected alternatives are for comparison purposes only, and may vary substantially if designs were developed for these systems. The approximate locations of non-selected mitigation alternative channels and basins are provided in in Figure 1 in Attachment A.

## Annual O&M Costs

It is anticipated that basins and channels will require routine maintenance, including debris removal, repairs to the lining and slopes, and revegetation after the work is complete. Maintenance costs were annualized from the future value using a discounted rate from Circular A94 Appendix C from the Office of Management and Budget for an assumed maintenance schedule of once every 10 years for a period of 20 years. Maintenance costs were derived from the annualized equipment and labor costs required to remove the 25- or 100-year sediment volume and replace the basin liner. Table 4 shows the estimated yearly maintenance cost.

Regional Alternative System	 l Maint. Cost 5-Year)	Annual Maint. Cost (100-Year)				
Basin 1	\$ 3,200	\$	6,300			
Basin 2	\$ 2,600	\$	5,100			
Basin 3	\$ 2,900	\$	4,600			
Basin 4	\$ 2,400	\$	5,100			
Basin 5	\$ 1,400	\$	2,700			
Basin 6 + Conveyance	\$ 4,600	\$	9,400			
Diversion Channel	\$ 12,600	\$	26,800			
Total	\$ 29,600		\$ 60,000			

## Table 4: Estimated Annualized O&M Cost for Each System Alternative

<sup>1</sup> Equipment Costs based on 2017 FEMA Schedule of Equipment Rates

<sup>2</sup> Maintenance costs includes riprap repairs, debris removal and disposal, and revegetation.

<sup>3</sup> Costs include labor based on 2019 labor rates for equipment operators from the US Bureau of Labor and Statistics.

## Lifecycle Cost Analysis

A life cycle present worth analysis was prepared for a 20-year period considering the estimated total project costs and the annual O&M costs. Salvaged and valuable materials such as soils excavated during construction and during routine maintenance were not considered in the analysis. The life cycle cost analysis and net present value (NPV) for each alternative are presented in Table 5.

#### SOUTH DAYTON VALLEY ADMP Engineer's Opinion of Probable Cost - May 22, 2020

#### GENERAL NOTE:

This preliminary estimate of probable construction cost is the Engineer's best judgement as a professional engineer generally familiar with this type of construction. However, since the Engineer has no control over market conditions, the Engineer does not guarantee that proposals, bids, or actual construction cost will not vary from this estimate.

25 Year SMA Basin 1

 Peak Inflow:
 303.8 (CFS)
 Date/Time of Peak Inflow:
 01Apr2019, 09:00

 Peak Discharge:
 162.0 (CFS)
 Date/Time of Peak Discharge:
 01Apr2019, 11:18

 Inflow Volume:
 96.5 (AC-FT)
 Peak Storage:
 33.4 (AC-FT)

 Discharge Volume:
 89.7 (AC-FT)
 Peak Elevation:
 107.0 (FT)

#### SMA Basin 2

Peak Inflow: 243.5 (CFS)	Date/Time of Peak Inflow:	01Apr2019, 08:36
Peak Discharge: 141.9 (CFS)	Date/Time of Peak Discharg	e:01Apr2019, 10:42
Inflow Volume: 73.4 (AC-FT)	Peak Storage:	25.3 (AC-FT)
Discharge Volume:68.2 (AC-FT)	Peak Elevation:	106.5 (FT)

#### SMA Basin 3

Peak Inflow:	101.0 (CFS)	Date/Time of Peak Inflow:	01Apr2019, 08:54
Peak Discharge:	44.3 (CFS)	Date/Time of Peak Discharge	e:01Apr2019, 11:36
Inflow Volume:	31.6 (AC-FT)	Peak Storage:	14.2 (AC-FT)
Discharge Volume	::27.5 (AC-FT)	Peak Elevation:	105.5 (FT)

## SMA Basin 4

Peak Inflow:	253.0 (CFS)	Date/Time of Peak Inflow:	01Apr2019, 08:30
Peak Discharge:	141.1 (CFS)	Date/Time of Peak Discharg	e:01Apr2019, 10:36
Inflow Volume:	69.1 (AC-FT)	Peak Storage:	23.2 (AC-FT)
Discharge Volume	:64.4 (AC-FT)	Peak Elevation:	106.5 (FT)

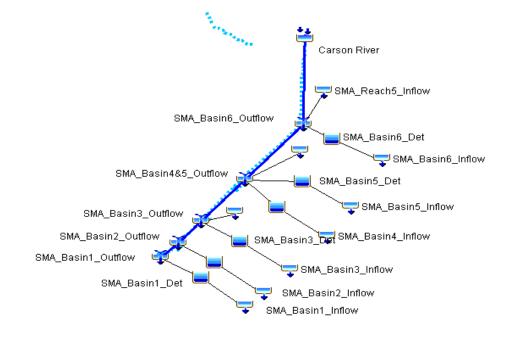

### SMA Basin 5

Peak Inflow:	90.8 (CFS)	Date/Time of Peak Inflow:	01Apr2019, 08:18
Peak Discharge:	29.8 (CFS)	Date/Time of Peak Discharge	:01Apr2019, 11:24
Inflow Volume:	23.9 (AC-FT)	Peak Storage:	12.3 (AC-FT)
Discharge Volume	:20.6 (AC-FT)	Peak Elevation:	105.5 (FT)

#### SMA Basin 6

Peak Inflow:	207.0 (CFS)	Date/Time of Peak Inflow:	01Apr2019, 09:12
Peak Discharge:	141.7 (CFS)	Date/Time of Peak Discharge	:01Apr2019, 10:42
Inflow Volume:	74.7 (AC-FT)	Peak Storage:	21.6 (AC-FT)
Discharge Volume	:69.9 (AC-FT)	Peak Elevation:	106.5 (FT)

Multi-Variable Regression for Alternatives Cost Analysis

#### SUMMARY OUTPUT FOR MULTI VARIABLE REGRESSION

#### Channels Input:

input.			
Channel	Length (ft)	Avg. Flowrate (cfs)	Cost
SMA 25 Year	30616.5	466	\$ 17,887,200
SMA 100 Year	30626.3	1181	\$ 26,308,800
Alt Channel 1	4200	790	\$ 1,883,505
Alt Channel 2	5500	918	\$ 1,850,400

#### Output:

Regression Statistics				
Multiple R	0.979813536			
R Square	0.960034565			
Adjusted R Square	0.440051847			
Standard Error	4512639.699			
Observations	4			

#### ANOVA

	df	SS	MS	F	Significance F	
Regression	2	9.78349E+14	4.89174E+14	24.02162157	0.142794148	
Residual	2	4.07278E+13	2.03639E+13			
Total	4	1.01908E+15
